These measures relate to fire types (surface, active crown, passive crown, etc.) and allow the fuels specialists to model and predict fire behavior.

DFPZ Maintenance Monitoring

Although the DFPZs were designed to remain effective for 10-years, monitoring will begin no later than 4 years after construction is completed. The monitoring plan would be completed at least every two years thereafter. Results of this monitoring would be available to the public. When surface fuel conditions reach a level of five to seven tons per acre, DFPZ maintenance activities may be necessary

Photo plot monitoring

Plots will be placed in RHCA's, edges of burn units (along roads and lines) and near areas of special resource concern. Private property, archaeological, botanical and wildlife sites are some of the areas of special resource concern. Plots will also be placed near areas with high fuel loading, logs and snags to show fire behavior, consumption and retention.

The Burn Boss and Fuel Officer will determine the photo plot location during burn plan development. GPS will be used to mark and establish plots for photo monitoring. Photos will be taken as the flaming front is passing through the plot area. Different angles might be taken to best illustrate fire behavior. Plots will be revisited one to two days after ignition to compare and contrast consumption and scorch. Revisits to plots will occur one, three and five years after ignition. Photos will be taken to illustrate scorch, mortality and regeneration.

Features that we want to display with photos:

Pre-burn—to show existing fuel conditions.

Photos during ignition - to show fire intensity/behavior.

Postburn—taken 1-2 days post ignition to show burn accomplishments (consumption, scorch)

Postburn—taken 1, 3, 5 years post ignition to show accomplishments and effects of fire behavior. (scorch, mortality, regeneration)

Appendix G Public Response to Comments

Freeman Project Response to Comments on the Draft Environmental Impact Statement

The Council on Environmental Quality (CEQ) regulation 40 CFR 1503.4 states that an agency preparing a final environmental impact statement (EIS) shall assess and consider comments both individually and collectively. The agency shall respond by one or more of the following means:

1. Modify alternatives
2. Develop and evaluate alternatives not previously given serious consideration
3. Supplement, improve, or modify its analyses
4. Make factual corrections
5. Explain why the comments do not warrant further agency response.

All substantive comments received on the draft EIS are included and the comment letters follow the Table.

Comment Coding Structure

As the comment letters were received, each was assigned a number for tracking purposes:

Letter Number	Commenter
1	U.S. Environmental Protection Agency
2	U.S. Department of the Interior
3	Northern Sierra Nevada Air Quality Management District
4	Sierra Pacific Industries
5	Sierra Nevada Forest Protection Campaign
6	Frank Stewart, Counties QLG Forester

Comments from each letter were then sorted by **subject** or resource area (for example, “Fire/Fuels”) and then by **category** (such as “Air Quality”). The comments in each comment letter were numbered sequentially from the beginning of the letter. Each code has the following format:

letter # - comment #

EXAMPLE:

Comment: EPA recommends that the cumulative impact [of all action alternatives on noxious weed invasion], which the DEIS identifies as moderate, be mitigated by reducing the acreage of group selection units where these species will likely become established.

Code: 5.68

Comments were taken from the letters verbatim. If some text needed to be added in order to clarify the intent, it is shown in brackets, as in the example above. Ellipses (. . .) are used if extraneous text was left out.

Master Code List

Subject	Subject Code	Category	Category Code	Definition
Forest Resources	FOR	General	100	General comment
		Canopy cover	101	Specific to canopy cover and crown closure
		Group selection	102	Specific to group selection
		Individual tree selection / area thinning	103	Specific to ITS
		Upper diameter limits	104	Specific to fuel reduction objectives, forest health
		DFPZ / WUI	105	Specific to location, size, adequacy, purpose
		Seral stage / size class	106	Specific to effects on habitat
Wildlife	WILD	General	200	General comment
		TES	201	Specific to TES (includes PACs, SOHA, LOPs, HRCAs), habitat
		Forest carnivores	202	Specific to forest carnivores, habitat / habitat connectivity
		MIS/Neotropical	203	Specific to MIS/Neotropical
Hydrology	HYDRO	General	300	General comment
		Riparian areas	301	Specific to riparian areas, Riparian Habitat Conservation Areas and Riparian Management Objectives
		Watersheds	302	Specific to watershed effects, restoration, Threshold of Concern, Cumulative Watershed Effects
Soils	SOIL	General Soil Disturbance	400	General comment
		Compaction	401	Specific to compaction
Botany	BOT	General	500	General comment
		Noxious weeds	501	Specific to noxious weeds
		TES	502	Specific to TES
Planning/Process	PLAN	General	600	General comment
		NFMA/Forest Plan/Framework	601	Specific to 1988 *Plumas National Forest Land and Resource Management Plan* (Forest Plan) and the 2001 and 2004 Sierra Nevada Forest Plan Amendments (Frameworks) that amend the Forest Plan
		NEPA	602	Specific to NEPA process
		HFQLG	603	Specific to HFQLG Act
		Proposed Action / Alternatives	604	Adequacy, proposes new

		EIS	605	Overall analysis, content, maps, Standards and Guidelines, indicator measures
Fire/Fuels	FUEL	General	700	General comment
		Air quality	701	Specific to effects from treatments (prescribed fire, mechanical treatments
		Air quality standards	702	Meeting or exceeding ambient air quality standards
Social/Economics	ECON	General	800	General economics/social comment
		Sawlog volume	801	Specific to economics of harvest methods
		Use of forest products / biomass	802	Specific to effects on local economy
Other	OTHER	General	900	General comment
		Transportation	901	Specific to system roads, OHV route designation process
		Scenery	902	Specific to scenery/viewsheds
		Recreation	903	Specific to recreation
		Heritage	904	Specific to heritage resources

Table H-1. Forest Service responses to comments received on the Freeman Project Draft Environmental Impact Statement. The comments are arranged by Subject Code then Category Code (see the Master Code List above). “Comment ID” refers to the number assigned to each comment letter followed by the specific comment number.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
ECON	801	4.04	Sierra Pacific Industry is concerned about the overall economic viability of the project . . . The defensible fuel profile zones and individual tree selection acres have a volume per acre less than 2 MBF . . . Helicopter logging is being proposed on 186 acres averaging less than 2 MBF per acre. The value of the sawlogs generated from these acres will not economically support this expensive harvest method. Units 87 and 93 also require removal of biomass by this harvest method. Yarding biomass with a helicopter cannot be supported by the sawlog value . . . All timber sale contracts require Project Activity l[L]evel Emergency Precautions, which potentially restricts the contractor’s amount of time and productivity for a sale during fire season. The economic analysis provided does not consider the cost implications related to operating a sale with these possible restrictions.	Based on further field review, sawlog volume per acre in the helicopter units would be less than originally estimated; therefore, these units may not be part of any timber sales or service contracts. The Forest Service recognizes that the volume per acre would be low even in the mechanical treatment units, but the treatments would take canopy cover down to the desired and/or minimum allowed. For a discussion of Project Activity Levels (PALs), please refer to the response to Frank Stewart’s comment (6.10).
ECON	801	6.05	What “decisions” regarding the transportation system in this project are being “coordinated” with the ongoing planning for designation of off-highway vehicle routes? What QLG funds are being used for this process . . .?	In an effort to not close roads that are identified in the Off-highway Vehicle (OHV) route designation process as receiving OHV use, the Forest Service is not closing them until after the OHV decision is signed (see footnote #1 in Table B.4 in Appendix B). No Quincy Library Group (QLG) vegetation or fuels funding would be used.
ECON	801	6.08	Are QLG funds being used for the chip seal to enhance the recreational use of 24N10 and 23N10Y at the Camp 5 boat launch facility?	Other sources of funding are planned.
FOR	101	6.01	Page 8, Table S-2: Crown Closure “%” targets should be	The number of acres not meeting the desired canopy cover

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			included for each alternative under the "Reduce Hazardous Fuels" portion.	for Defensible Fuel Profile Zones (DFPZ) and Area Thin are displayed in Table 2.5 of the Draft Environmental Impact Statement (DEIS). The number of acres meeting the desired condition will be added to the Final Environmental Impact Statement (FEIS).
FOR	101	6.06	Group canopy closure measures are not to be included in DFPZ or ITS units.	The Herger-Feinstein Quincy Library Group (HFQLG) Implementation Team has provided direction that requires canopy cover be calculated by factoring in the groups in the area thinning units and not factoring the groups into the DFPZ units. (April 20, 2005)
FOR	102	4.02	The proposed project has 175 acres identified for treatment using group selection. According to our calculations using a 20-year cutting cycle we estimate that 900 acres could be treated by group selects.	If the Forest Service uses a 20-year cutting cycle, the project would generate approximately 500 acres of groups in the approximate 4,300 acres proposed for mechanical thinning. However, not all of the mechanical thinning would be in commercial-sized stands (average diameter of 12" diameter breast height (dbh) or greater). The Freeman area was heavily salvaged from the late 1980s into the mid 1990s and is already full of small under-stocked patches. These small patches are not factored into the size class designations for the seral stage analysis (in other words, they usually are small enough that a separate stand is not broken out and called size class 0-1). The seral stage analysis done for the project indicates that there is no need for additional early seral habitat, but there is a significant need to develop late seral habitat. The group selections would be placed in areas where there are forest health issues (such as mistletoe, root disease, or bark beetles) to the extent that the Forest Service could make these areas economic to treat as a timber sale.
FOR	103	4.03	The agency may want [to] consider thinning adjacent stands within the project area that contain more volume per acre to help offset the costly low volume per DFPZ and ITS acres.	All stands outside the DFPZ that were not part of Spotted Owl Habitat Areas (SOHAs) or Protected Activity Centers (PACs) that had sawlog-sized trees of sufficient density and

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
				could be accessed for harvest (even by helicopter) were considered for thinning. Some were not treated due to heritage, watershed, or other resource issues.
FOR	104	5.16	The DEIS and Fire and Fuels Report (FFR) do not attempt to justify the Forest Service's assumption that the logging of larger, co-dominant trees (up to 30" dbh) is necessary to avoid stand replacing fires.	Logging of larger codominant trees up to 30" dbh is not necessary to meet fuel reduction objectives; however, the logging of trees between 20" and 30" dbh that are in subordinate crown positions and/or are at high risk of mortality (above those needed for snag recruitment) is necessary to make the project cost effective. Other objectives of the project are to improve forest health and contribute to the economic stability of the community.
FOR	104	5.18	The Forest Service does not provide any explanation why it is necessary to log trees above 20" to improve forest health.	Harvesting trees above 20" dbh that are in subordinate crown classes and/or are at high risk due to disease and insects improves forest health. For more discussion on this subject, see page 108-109 of the FEIS (pages 109-110 of the DEIS).
FOR	105	6.04	Your assumption that DFPZ's are being constructed to prevent ground fires from turning into crown fires within the DFPZ is incorrect. The QLG DFPZ network is being strategically constructed to break up landscape hazardous fuel conditions and bring "oncoming crown fires" to the ground and give safe working locations for fire fighters to initiate fire suppression activities.	The Forest Service agrees with the commenter; however, the statement in the DEIS is not defining what a DFPZ is, but rather it is referring to existing surface fuel conditions and live crown base heights and the potential for a fire to move from the ground surface to the forest canopy under 90th percentile weather conditions.
FOR	105	6.07	What is the reason for separating WUI and DFPZ acres when both the HFQLG Act and Healthy Forest Restoration Act support the acre designation and treatments?	The HFQLG Implementation Team has provided direction that requires the Forest Service to treat the Wildland/Urban Interface (WUI) outside of the DFPZ according to ITS Standards and Guidelines. The WUI is up to 1.5 miles wide while the DFPZ is generally up to 0.5-mile wide. The 2004 Framework modeled treatments in the HFQLG Pilot Project area with the WUI having a 50% canopy cover.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
FUEL	701	1.02	. . . while the DEIS contains information regarding air quality mitigation for prescribed burning (p. 76), there is no information regarding mitigation for air impacts that result from mechanical thinning.	In the FEIS the Forest will calculate and display the smoke related emissions from PM 2.5 by alternative clearly demonstrating the insignificance of the mechanical treatment emissions (FEIS pg. 88-89, 98-103)
FUEL	701	3.02	. . . the District recommends that careful surveillance of smoke generated by the project be performed, in order to document the source of any smoke that may work its way into the Portola or Graeagle area, or any other populated area. This should include written descriptions of smoke behavior and time- and date-stamped photographs from high points on the landscape or aircraft, preferably at least twice per day while burning is taking place.	The Smoke Management Plan included in every Prescribed Burn Plan requires that smoke travel is monitored closely during all phases of the project. Photographs and written descriptions of smoke dispersal are included as part of the monitoring, which is contained in the project record.
FUEL	701	3.03	. . . the District strongly recommends that the Forest Service coordinate early in the planning process with local businesses involved with using woodwaste for power generation or other purposes . . ., in order to make as much waste vegetation available to these businesses as possible. Such methods of disposal . . . result in lower levels of air pollution emissions and are therefore preferable to open burning.	Alternative 4 was designed with the intent of removing more fuels in the form of biomass in order to provide wood waste for power generation and to reduce emissions from open burning. Table 2.5 (under “Cost Effectiveness and Support of Local Communities”) shows the reduction in the amount of pile burning (in acres) and number of piles associated with Alternative 4. Additional text has been added to the “Comparison of Alternatives” section in Chapter 2 and the “Fire, Fuels and Air Quality” section in Chapter 3. DEIS Pg. 119 of the Forest Resources Report discusses generation of power as an advantage of mechanical thinning.
FUEL	702	3.01	The EIS should specifically discuss ambient air quality standards in the area and address the potential and consequences of exceeding them.	See Forest Service Response 1.02. The FEIS also discloses the steps involved in avoiding exceedance that every prescribed burn undergoes.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
HYDRO	301	5.23	Harvest activities in the Riparian Habitat Conservation Areas (RHCAs) are regulated by the direction in the 2004 ROD…The 2004 ROD directs the HFQLG forests to follow the SAT Guidelines as presented in the 1998 QLG ACT and partially represented in Appendix L of the HFQLG FEIS…provide for the removal of timber from RHCAs only when necessary to “acquire desired vegetation characteristics needed to attain Riparian Management Objectives.”…Further, the SAT guidelines explicitly “prohibit scheduled timber harvest” in RHCAs and “prohibit activities…that are not designed specifically to improve the structure and function of the Riparian Habitat Conservation Areas and benefit fish habitat.”... These directives mean that the RHCAs are to be harvested only if that activity maintains or restores the natural structure and function of the area. . . . Alternatives 1, 3 and 4 harvest at an intensity beyond what is necessary to meet the Riparian Management Objectives. A review of the Vegetation Report and Fire and Fuels Report indicates that it is not necessary to reduce canopy to 30% and remove trees over 20” dbh to increase the fire resiliency and reduce stand density of the affected stands. . . . Thus, the objectives supported by the SAT guidelines to increase fire resiliency and improve forest health can be achieved by limiting reduction of canopy cover to 50% and to retaining trees over 20” dbh. . . . SAT requires that Riparian Habitat Conservation Areas be established and that watershed analysis be completed at appropriate scales for habitat protection and restoration. . . . Several subwatersheds in the Freeman DEIS are at or approaching TOC… Val (U) and Cow (U) are at high risk of CWEs. The Freeman DEIS fails to explain how logging in these high risk watersheds will benefit the RHCAs and meet the Riparian Management Objectives in the SAT Guidelines.. above….	Canopy retention in the Riparian Habitat Conservation Areas (RHCAs) would be a minimum of 40% and 60% where available (see page 49 in the DEIS). The inner RHCAs (25’ along each side of the stream channel) would be hand thinned to an upper diameter limit of 8” dbh, beyond the reach of the boom arm and on slopes greater than 15%, except in aspen treatment areas. The rationale for treatment of the RHCAs is provided for in the FEIS, Appendix H. The existing condition prior to treatment is well below threshold. The short-term increase in ERAs resulting from this action would be significantly lower when compared to predicted increases in ERAs resulting from a high-intensity fire, for additional discussion, see the RMOs (Appendix H of the FEIS). A Rapid Landscape Assessment was completed for the project area prior to the development of the Proposed Action. Most of the elements required for a Watershed Analysis were provided for in this document. The rapid landscape assessment formed the foundation for our Proposed Action, Purpose and Need on this project area. In addition, a Draft Watershed Analysis was developed for the watershed and will be finalized prior to the signing of the decision.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
PLAN	601	5.20	The Campaign reiterates its prior comments that the environmental review document must assess an alternative that implements the 2001 ROD standards to determine whether project objectives can be met with less significant impacts on wildlife. . . . The Forest Service’s alternatives analysis establishes a false choice between 3 similar “action” alternatives and no treatment whatsoever. This is not a reasonable approach under NEPA. . . . In response, the DEIS (p. 83) states that an alternative based on the 2001 ROD is not required because this issue is “already decided by law.” The DEIS does not explain how or why an alternative based on the 2001 ROD would be inconsistent with the 2004 ROD, so we cannot respond to this claim in detail. However, with limited exceptions, the QLG pilot project can be implemented consistent with the 2001 ROD. (USDA Forest Service 2001b, p. 50).	The inapplicability of the 2001 Sierra Nevada Forest Plan Amendment (SNFPA) Record of Decision (ROD) has already been decided (that is why Alternative 9 was not analyzed in detail—see section 2.1.3.5 in Chapter 2 of the Freeman Project DEIS and FEIS). The 2004 SNFPA ROD replaced the 2001 SNFPA ROD in its entirety. The Responsible Official will take into consideration all of the potential effects of the alternatives at the time of the decision. The DEIS (and FEIS) contain two additional action alternatives to the Proposed Action that were studied in detail, as well as a description of five alternatives that were considered but eliminated from detailed study. Therefore, a number of alternatives were considered in the EIS (see Chapter 2). Further clarification has been provided in the FEIS.
PLAN	604	1.01	Alternative 3 would have fewer impacts to habitat, soil resources and watersheds than Alternative 4 while meeting the project’s Purpose and Need.	The comment will be factored into the Deciding Officers decision.
PLAN	605	2.01	[The commenter highlights grammatical and typographical errors only.]	The FEIS corrects these errors.
PLAN	605	5.17	The DEIS and [Fire and Fuels Report] (FFR) reiterate the goal of fire risk reduction, without ever setting forth measurable standards that can be evaluated.	Table 2.5 (“The Freeman Project Purpose and Need and Issues Objectives Comparing Each Alternative and the Proposed Action”), page 64, under “Reduce Hazard Fuels,” does show measurable standards that were evaluated by alternative.
PLAN	605	5.21	In response, the DEIS (p. 82) states that the Forest Service	Further clarification has been provided in the FEIS.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			has already determined that this alternative does not meet its Purposes and Needs in prior Forest Service projects Happy Jack, Empire and Watdog and that there "was no difference in effects to watershed, wildlife or fuels objectives." There are numerous problems with this analysis.	
PLAN	605	6.13	You need to include the unit numbers with the units. The maps are small and cluttered and a larger scale would help the reader.	The FEIS provides unit numbers on the maps. As noted in the Forest Service scoping letter for the Freeman Project, a larger-scale map is available upon request at the District office.
SOIL	400	4.01	Soil protection measures recommend skid trail spacing would generally average 120 feet center to center.	The DEIS has been revised to state "Generally use skid trail spacing averaging 80 to 120 feet . . ." (see page 539 of the FEIS). This reflects recent discussions held with Forest Service specialists and industry representatives.
SOIL	401	5.25	The Freeman DEIS Soils Analysis p. 338 displays the level of compaction in various unit areas in the project area in Table 3.74. Even with sub-soiling, the level of compaction is significantly higher in several units than the Plumas Forest Plan allows. . . . The DEIS states at p. 337 the historic condition of "three units" (actually it is four units) 1, 9, 48, 74 are over 15% compacted. These same four units remain over 15% compacted post-treatment and two additional units would experience increases of >15% compaction post treatment. This is a violation of NFMA and the existing PNF Forest Plan Soil Quality standards.	Monitoring and mitigation have been added to the FEIS to do additional subsoiling in these units if it is needed (see page 78, 556).
SOIL	401	5.26	All three of the action alternatives involve significant logging (mechanical treatments) in the RHCAs (Alt 1-840 acres; Alt 3-750 acres; Alt 4-747 acres). The DEIS fails to disclose the specific levels of historic compaction in RHCAs	The level of compaction is displayed In the existing condition (Table 3.74). Equivalent roaded acres (ERAs) are analyzed for each alternative, as a measure of loss of hydrologic function resulting from compacted surfaces.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			or the amount of project-related compaction in the RHCAs under the various alternatives.	Cumulative effects on the RHCAs are reflected in the ERA analysis for sensitive areas (DEIS Table 3.77). Sensitive areas/RHCAs are typically defined as those within 200' of perennial streams; however, to build more sensitivity into the ERA analysis, the assessment focuses on the sensitive areas near the stream channel network, including riparian areas, meadows and wetlands (Page 342, DEIS).
WILD	201	5.01	The Freeman Project is located in the vicinity of Area of Concern (AOC) Nos. 1 and No. 2 for the California spotted owl . . . Any further reduction of habitat in this region thus threatens long term owl viability	The Wildlife Effects of the DEIS Pg. 170 (FEIS Pg. 207) make it clear that the Freeman Project is not located in any Area of Concern(AOC), nor does the Freeman Project have the characteristics described for why an area has been designated an AOC. The AOCs were designated in the California Spotted Owl (CASPO) guidelines, which have been replaced by the Standards and Guidelines of the 2004 SNFPA ROD. AOC 1 is 28 miles to the north of the Freeman Project and AOC 2 is 20 miles to the northwest of the Freeman Project area. This distance is not considered "in the vicinity".
WILD	201	5.02	… there is substantial uncertainty and thus substantial cause for concern regarding the owl's population throughout the Sierra Nevada, within the Plumas National Forest and within the Freeman Wildlife Analysis Area. [The SNFPC noted the history of the petitioning process.]	Although it is true that the United States Fish and Wildlife Service (USFWS) has been petitioned by the commenter to list the California spotted owl, the comment letter does not include the most recent 12-month finding by the USFWS posted on May 24, 2006, in the *Federal Register* (Vol. 71, No. 100, 50 CFR Part 17) which states that "after reviewing the best available scientific and commercial information, we find that the petitioned action is not warranted." And then goes on to state . . . "Existing habitat used by California spotted owls appears to be vulnerable to stand-replacing catastrophic fire. " . . . "However, . . . the best-available data indicate the SNFPA

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
				does adequately protect spotted owl habitat while lessening the threat of wildfire and that it includes many restrictions and guidelines that limit the proportion of areas that can be logged.” . . . “On the basis of this review, we find that the listing of the California spotted owl is not warranted at this time because: (1) The best-available data indicate that California spotted owl populations are stationary throughout the Sierras, ... (2) We anticipate that planned and currently implemented fuels-reduction activities in the Sierras . . . will have a long-term benefit to California spotted owls by reducing the risk of catastrophic wildfire... (3) Although survey data for spotted owls in southern California are incomplete, the best-available data do not show statistically significant declines.. . . . “ These findings were published the day that the Freeman Project DEIS was sent to the public for comment; these findings have been incorporated into the Freeman Project FEIS.
WILD	201	5.03	Extensive logging within HRCAs is likely to adversely affect owl reproduction and occupancy. . . . …the Freeman Project proposes to log approximately 630 acres of owl home range core areas. In particular, the Project will reduce suitable HRCA habitat from 597 to 310 acres in PL203, a reduction of 48% and from 476 to 134 acres in PL204, a reduction of 72%. (DEIS, p. 227, Table 3.47.) The remaining suitable habitat in these HRCAs will be 44% (310/700 acres) for PL203 and 17% (775/134 acres) for PL204. . . .	Table 3.46, page 227 in the DEIS shows there is a potential risk to PAC viability/owl occupancy after treating HRCAs. However, it has been determined that the Freeman Project “may affect, but is not likely to adversely affect or cause a trend toward federal listing “ for the spotted owl. For a correct interpretation of the impacts on owl HRCAs, see Table 3.47 on page 227 in the DEIS, (Tables 3.41 and 3.42 Page 201-227 in the FEIS). The Wildlife BA/BE pages 90-94 and DEIS pages 226-232 disclose the effects on owl viability from logging within HRCAs. Specifically, pages 227-228 of the DEIS discuss the analysis and explains the potential high risk to viability.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			Further, both the DEIS and BE confirm that existing habitat may already be inadequate to support owls in the Wildlife Analysis Area. . . . The DEIS notes that logging within HRCAs and home range areas may increase competition among remaining owl pairs, but offers no analysis of why such loss of quality habitat does not pose a high risk for the owl.	
WILD	201	5.04	The Forest Service dismisses the impacts of harvesting co-dominant conifers between 20-30" dbh. *See* DEIS, p. 82. . . . Similarly, in the Freeman Project, the Forest Service provides no information as to how many larger co-dominant conifers will be removed, except to provide information that over 3,000 acres of suitable habitat will be eliminated.	The information on page 82 of the DEIS addresses alternatives that were dismissed from analysis. The impacts on spotted owl due to changes in structural components caused by fuels reduction treatments are discussed in the DEIS on 224-226 and Table 3.29. Further clarification for why this alternative was not analyzed has been added to the FEIS in the "Alternatives Eliminated from Detailed Study" section (Freeman Project FEIS, Chapter 2). This alternative was analyzed on the Plumas National Forest in both the Watdog Project on the Feather River Ranger District and the Empire Project on the Mt. Hough Ranger District. It was also analyzed on the Beckwourth Ranger District. In all three analyses, it was shown that this alternative would neither meet the purpose of the project nor resolve the need for the project. The alternative would not fully implement fuel treatments to be tested under the HFQLG Pilot Project. The analyses indicated a higher probability of crown fire. It also reduced the economic contribution. And did not allow for the removal of dead and dying trees in that diameter range. Trees in the size range of 20 to 30 inches dbh have over twice the value of smaller trees and much greater board foot volume. Though fewer of these large trees have to be removed compared to smaller diameter trees, they greatly increase the economic feasibility

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
				and efficiency of the project by providing much-needed value. The Watdog Project demonstrated an approximate 115 percent loss of net revenues and 50 percent loss in potential job creation under an alternative that proposes a 50 percent canopy cover and a 20-inch dbh limit compared to an alternative that proposes a 40 percent canopy cover and dbh limit of 30 inches. Similarly, the Empire Project showed an approximate 40 percent loss in net revenues and 10 percent loss in job creation. The economic feasibility of the Freeman Project is likewise tied to the removal of trees with a dbh limit of 20 to 30 inches. Furthermore, these analyses indicated that there would be little difference in adverse environmental effects, at a landscape or project area level, in treating stands to 40 percent canopy with a dbh limit of 30 inches versus treating stands to achieve a 50 percent residual canopy cover with a dbh limit of 20 inches.
WILD	201	5.05	. . . because the project implements the 2004 Framework and QLG project, the DEIS (p. 234-235) concludes that the project "would not contribute to a trend toward listing nor cause a loss of viability." . . . Therefore, the fact that this project implements the 2004 ROD in no way ensures the owl's viability. The 2004 ROD and FSEIS did not analyze the site-specific impacts of logging pursuant to the Freeman and similar projects. Rather, the FSEIS deferred detailed analysis of environmental impacts to future site-specific projects, such as Freeman. As discussed above, however, the Freeman Project DEIS does not provide any analysis or basis for why further cutting in critical owl habitat and further reduction of owl habitat home range will not contribute to long term	No activities will occur in PACs and SOHAs, which are the areas historically known to be used by spotted owls. Of the potential suitable nesting habitat, 94%-96% would be retained in the analysis area under all action alternatives. Of the potential suitable foraging habitat, 84%-86% would be retained in the analysis area under all action alternatives. For example, the discussion on page 89 in the BE shows that the total current foraging habitat in the Freeman Project area is 18,684 acres. Of these 18,684 acres, 2,610-3,037 acres (14%-16.3% of 18,684 – see Table 3.44) would be affected (or 84%-86% would not be affected) by proposed treatments. Therefore, this would not contribute to a loss of owl viability under the Freeman Project and is not considered a significant adverse impact. Potential effects of the No-action Alternative are discussed

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			population decline. Given that the analysis in the BE demonstrates the possibility of significant adverse impacts to the owl and its habitat, there is no legitimate basis for concluding that the Freeman Project will not threaten owl viability, despite the fact that it is being carried out pursuant to the 2004 ROD.	in the BE. Fuel loads left untreated, would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable owl nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. If a large fire occurred suitable owl habitat could become patchy and could lead to reduced or lower abundance of owls within the Wildlife Analysis Area. The amount of nesting and foraging habitat retained under the action alternatives is above and beyond those acres retained within PACs and SOHAs in the anaylsis areas
WILD	201	6.02	Mr. Steward made several comments that questioned why the Forest Service did not consider thinned stands with 40% canopy cover as suitable owl habitat.	The 40% crown closure is still suitable; however, after the understory structure components are removed, the habitat would be unsuitable. Suitable owl habitat contains three basic components; Canopy cover, multi-layered tree structure and snags & down woody debris. All three of these components need to be retained in order to maintain suitability.
WILD	201	6.03	… Table [S-2.]: You show nesting habitat losses for three critters when in reality it is the development of additional foraging habitat for each of these critters.	The removal of understory structural components from the habitat leads to unsuitable foraging and nesting habitat. See Comment ID 6.02
WILD	201	6.09	What efforts are being undertaken to reduce the number of LOP’s and associated time constraints?	Surveys have been conducted in the project area to minimize the need for Limited Operating Periods(LOPs) during project implementation. At this point, we anticipate that 5 of the 14 LOPs would be necessary. These LOPs are for the spotted owl, northern goshawk, great gray owl, bald eagle and a bald eagle winter roost. These 5 LOPs were mapped and reviewed by contracting personnel and were felt to be feasible.
WILD	201	6.10	In addition to the reduced operating time from the wildlife	The new PAL measures are weather dependent and there

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			species LOP's, what is the operating and cost effect of the new PAL measures on the proposed operations? These operational delay costs must be clearly displayed in the FEIS.	currently is no way to predict the impact.
WILD	201	6.11	Why are you treated PAC's 203 and 204 to the level that owls will abandon them when the HFQLG-Act says to stay out of PAC's? . . . Why are you applying HRCA land designations when the Act only calls for PAC's and SOHA's?	The PACs would not be treated; however, the Home Range Core Areas (HRCAs) surrounding the PACs would be treated, potentially putting the PAC occupants at risk. The Forest Service is disclosing the impacts on HRCAs on a project-specific basis, but it is not applying the Standards and Guidelines of the 2004 Framework for HRCA land allocation. In addition, tracking impacts to HRCAs is needed now for use in assessing impacts to owls once the Act expires.
WILD	201	6.12	I urge you to read the most recent scientific Meta analysis and the Fish and Wildlife Spotted Owl Findings to correctly state the habitat concerns and requirements of the owl.	This new information has been considered in the FEIS.
WILD	202	5.06	. . . habitat changes that would alter the marten's preferred habitat, such as the changes that would result from the Freeman Project, could reduce the marten's range and distribution and lead to local extirpation. . . . Overall, the Freeman will render approximately 3,416 acres of habitat for the marten unsuitable. (DEIS, p. 250). This habitat reduction is particularly problematic given that the marten has not been detected in the project area in recent years, thereby raising the likelihood that this area may presently act as a barrier to habitat connectivity within the Plumas National Forest.	Indeed, 3,416 acres of the 24,826 acres of potential marten habitat could be affected by proposed treatments. However, this amount of affected acres would not lead to local extirpation of a species that is currently not present in the project area. The remaining 21,410 unaffected acres (86.3%) would still provide suitable marten habitat and habitat connectivity to other suitable marten habitat on the Plumas National Forest and other private lands. Pages 250-254 in the DEIS provide detailed discussions on potential effects on the marten, fisher and draft Forest Carnivore Network. Approximately 7,364 acres of suitable Draft Carnivore Network habitat are located within the Wildlife Analysis Area. Depending on which Alternative is chosen, between 692 and 897 acres of suitable habitat in the Draft Carnivore Network would be effected by the Freeman Project (BE/BA

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
				Pg. 143).
WILD	202	5.07	. . . the conclusion in the BE (p. 147) that the Freeman Project is not likely to threaten the viability of the marten or contribute to a trend towards federal listing under the Endangered Species Act "is not supported by analysis in the record." (Kucera 2004a, p. 3; *See also* Kucera 2006.)	Page 147 in the Wildlife BA/BE shows that a high percentage of habitat would be retained for the marten (which currently is not present in the project area) and explains that the fuel treatments would contribute to a reduction in habitat loss from wildfire. Page 144 in the DEIS explains that habitat connectivity would be maintained across the Forest. To date across the HFLG pilot area suitable habitat (5M, 5D, & 6) affected amounts to only 1.7%o the habitat available. This amount is minimal and does not pose a risk to Marten viability.
WILD	202	5.08	The Pacific fisher is a forest carnivore that is closely associated with older forests with medium and large trees, dense canopy cover and abundant large snags and down wood. The Freeman Project would degrade fisher habitat by logging medium and large trees, reducing canopy cover and removing large snags and down logs.	The wildlife terrestrial habitat effects from the action alternatives are discussed on pages 195-201 in the DEIS with particular discussion about the specific amounts of existing large trees, snags, large woody debris and canopy cover reductions. The effects to forest carnivore habitat components are discussed on pages 249-252 of the DEIS.
WILD	202	5.09	The DEIS and BE fail to disclose the ecological significance of the project area. The Freeman Project is located just south of Areas of Concern that threaten north-south habitat connectivity for owls, forest carnivores and other sensitive species. Yet the role of the Project and Wildlife Analysis Areas in furthering the necessary habitat connectivity is not provided in the planning documents.	The Forest Service acknowledges that the Freeman Project area is an ecologically diverse area. The proposed DFPZ, group selection and area thinning treatments may not further habitat connectivity in the short term, but would further the protection of habitat from wildfire and improve forest health—both of which would contribute to habitat connectivity over the long term. See pages 195-201 in the DEIS.
WILD	202	5.10	The DEIS and BE fail to include accurate information and analysis regarding the location and amount of suitable spotted owl nesting habitat currently within the project area and the amount that will be rendered unsuitable if the project is implemented.	Please see pages 224-225 and Table 3.44 in the DEIS.

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
WILD	202	5.11	The DEIS/BE do not adequately assess the critical factor for owl persistence which is high quality, 5D and 6 habitat, that supporting adult survivorship. . . . In other words, habitat that supports adult survival, not reproduction, is the critical factor for land managers to address.	The Wildlife Analysis Area for the Freeman Project was developed to include owl PACs/SOHAs/HRCAs that would incur potential direct, indirect and cumulative effects on California spotted owl PAC and HRCA distribution. Therefore, the Wildlife Analysis Area for the Freeman Project goes out to and encompasses the closest PACs/HRCAs in the project area. The Wildlife Analysis Area totals approximately 46,039 acres, of which 41,388 acres are National Forest lands. There are a total of 7 PACs/SOHAs/HRCAs included in the Wildlife Analysis Area. Changes to suitable owl habitat, including California Wildlife Habitat Relationships (CWHR) size class 5D, across this analysis area have been disclosed in the Wildlife BE/BA and DEIS. Table 3.31 of the DEIS displays the amount of "Spotted Owl Habitat on National Forest Land by CWHR Type." There are approximately 6,306 acres of CWHR size class 5 in the Wildlife Analysis Area. Table 3.44 displays the effect of the action alternatives on potential spotted owl nesting and foraging habitat. Approximately 94% of the CWHR size class 5 would remain under the preferred alternative. There is no mapped CWHR size class 6 in the project area.
WILD	202	5.12	. . . the Freeman DEIS and BE acknowledge the poor habitat quality for sensitive forest species between owl PACs and SOHAs, yet do not provide adequate information as to overall quality of home range and HRCA habitat for owls existing in the Wildlife Analysis Area.	Table 24 in the Wildlife BA/BE displays the amount of suitable habitat present in the three HRCAs and how the amounts would be modified by each action alternative.
WILD	202	5.13	6. DEIS Fails to Analyze the Significant Impacts to Spotted Owls by Increasing the Presence of Spotted Owl Predators and Reducing Owl Prey Base	Pages 232-237 in the DEIS address the issue of spotted owl predators and its prey base. Barred owls are currently not present in the project area. Great horned owls are present in the project area and may increase, but the response of the

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
				great horned owl and spotted owl to treatments is not known. With the growth of early successional habitat (brush and seedlings) following treatment and the retention of downed logs and woody debris, small mammals (such as woodrats) would recolonize the area sooner.
WILD	202	5.14	7. The DEIS Fails to Analyze the Inadequacy of Present Habitat in the Project and Wildlife Analysis Area to Support Martin and Fisher	Pages 182-188 in the DEIS discuss the type of habitat preferred by fisher and marten (that is, “suitable habitat”). There are approximately 25,000 acres of suitable habitat in the Wildlife Analysis Area (see Table 3.36 in the DEIS) to support fisher and 25,000 acres of suitable habitat (see Table 3.37 in the DEIS) to support marten.
WILD	202	5.15	The Freeman Project DEIS and BE do not provide an adequate discussion of the cumulative impacts and location of past, present and planned projects in the vicinity of Freeman [Project] that are likely to affect owl or forest carnivore habitat.	The cumulative effects analysis for each resource was based on the boundary of each specific resource analysis area (which can extend beyond the project area). For example, the Wildlife Analysis Area extends to a point at which no direct or indirect effects would be discernable and would not act cumulatively with other actions. This Wildlife Analysis Area boundary for terrestrial wildlife was delineated based on the potential direct, indirect and cumulative effects on California spotted owl PACs, HRCAs and breeding home range distribution. The Freeman project area encompasses the next outlying HRCA beyond where project activity would occur. See page 29 in the BA/BE. This analysis area was used for all wildlife species since project effects to these species would not be felt beyond this analysis boundary.
WILD	203	5.19	The Freeman DEIS/MIS Report claim that the thinning and fuels reduction treatments will benefit Mule Deer by allowing for increases of brush species as a result of treatments (MIS report p. 12). This is a misleading statement based upon the stated object[ive]s in the DFPZs and GS units in Freeman and throughout the [Q]LG project area.	Mule deer are used as a habitat indicator for early seral shrub habitats. The creation of mule deer habitat is not an objective of DFPZ and groups selections; rather, the creation of habitat for mule deer is a direct result (beneficial effect) of the treatments (including logging, fire, area thinning and group selection). See pages 12-15 in the MIS report. Also refer to

Subject Code	Category Code	Comment ID	Comment	Forest Service Response
			The Forest Service has no quantitative data to document habitat use in the project area for winter range, fawning habitat, summer range, or migration corridors	Table 3.19 of the DEIS. The most current population and trend data available and data from several differing censusing methods have been added to the FEIS in the Chapter 3 Wildlife Section. Habitat trends and use are also discussed, as are the condition of forage and impacts of management actions.
WILD	203	5.22	The Freeman DEIS is flawed in its analysis of direct, indirect and cumulative impacts on gray squirrel (see cumulative impacts discussion below). To analyze the cause and effect of the project to populations of this species, the habitat and population concerns must be address with scientifically sound quantitative analysis and monitoring methodology. There have been no surveys or monitoring (for the woodpecker group) conducted on the Plumas National Forest in spite of the fact that both the SNFPA Section 3.2.3. and the 1999 H-F QLG ROD/FEIS revealed significant habitat declines for several MIS based on the 5-year QLG Pilot Project (Freeman DEIS p. 259; 1999 QLG EIS p. AA-19).	The Woodpecker Group and gray squirrel are not identified as Management Indicator Species (MIS) in the 1988 *Plumas National Forest Land and Resource Management Plan* ("Forest Plan") Appendix G and are therefore not subject to Appendix E of the 2001 Sierra Nevada Forest Plan Amendment (2001 Framework). For the Woodpecker Group and gray squirrel, the Monitoring Plan for the Plumas Forest Plan speaks to monitoring habitat, specifically with regards to meeting Standards and Guidelines for snags and hardwoods and does not discuss monitoring populations of woodpeckers and gray squirrels. The effects of the Freeman Project and subsequently woodpecker species and gray squirrels, are collectively discussed in the Freeman Project Wildlife Supplemental Report.
WILD	203	5.24	II. The Freeman DEIS fails to identify how the project's RHCA logging will benefit these key riparian and aquatic management objectives (particularly #7) since the DEIS lacks specific data on population trend and habitat quality and needs for the aquatic-riparian MIS/SARs in the 2004 SNFPA Appendix E-98 Table 11. The DEIS suggest[s] that Trout/MIS populations suffer from a lack of clean spawning gravels. How will logging in RHCAs improve this existing condition?	The RMO analysis discusses the benefit of doing fuel reduction in the RHCA and will be added to the FEIS (Appendix H). Habitat quality was discussed under the Water Quality section of the DEIS. For further discussion on Trout/Management Indicator Species (MIS) populations, the MIS are being revised and will be incorporated in the FEIS.

Appendix H Riparian Management Objectives

Riparian Management Objectives

In general, the HFQFLG-EIS guidelines prohibit activities within the RHCA unless they are specifically designed to improve the structure and function of the RHCA and benefit fish habitat. The RMOs in Appendix L of the HFQLG-EIS that specifically relate to Hydrology and apply to the construction of the DFPZ and operations within RHCAs are presented below:

The following riparian management objectives would apply to the Freeman DFPZ and GS Project. Under all action alternatives, treatments are proposed within many of the RHCAs. In the discussion that follows, most references to treatment within RHCAs are specifically limited to those treatment areas. No RHCA treatment would occur under the No-action Alternative. Under all action alternatives some level of aspen release would occur. In these stands, conifers less than 30-inches dbh that are encroaching on aspen stands may be removed.

The objective of the RHCA treatments within treatment units is to reduce the potential for adverse impacts from high intensity wildfire. Historically, fire has been an integral disturbance agent in riparian systems (Dwire and Kauffman 2003). However, fire suppression has reduced the influence of fire, resulting in fuel accumulation and increased likelihood of large, severe wildfires (Taylor and Skinner 1998). These RHCA treatments would provide a safer and more effective fire suppression environment, improve forest health and provide for a more sustainable vegetation condition consistent with protecting and maintaining riparian habitat values, as discussed below. Field surveys were conducted to verify the existence and condition of the streams within units that would be mechanically treated. All RHCA treatments are designed to minimize erosion from soil disturbance and to protect and maintain the riparian vegetation that provides bank stabilization and habitat for wildlife, fish and other aquatic species. The ten riparian management objectives for the Project are discussed below.

1) Maintain or restore water quality to a degree that provides for stable and productive riparian and aquatic ecosystems. Water quality parameters that apply to these ecosystems include timing and character of temperature, sediment and nutrients.

In addition to reducing the risk of high-intensity fires, thinning RHCAs will allow the ecosystem within this corridor to return to a more productive historic condition. Competition between co-dominates and dominant trees will decrease and growth rates will increase while mortality rates decline. Over time, the crowns of larger more fire resistant trees will fill in increasing the necessary shade for temperature regulation. Retaining 60 percent crown cover, where available, along fish baring streams and 40 percent everywhere else except aspen units will maintain adequate cover in the interim.

Thinning which will occur throughout most RHCA's within the project area would encourage forest growth, which would hasten the development of larger trees and the recruitment of large woody debris to stream channels. Large woody debris is generally scarce throughout the RHCA's due to a shortage of old growth vegetation. In addition, thinning overstocked RHCAs can decrease tree mortality. Reducing tree mortality within the RHCA will mean less risk of debris jams. Reducing the quantity of dead and downed trees inside the channel will result in fewer point erosion sources. This point source erosion is caused when hydrologic forces erode the bank around the ends of woody obstructions in otherwise stable channels. Reducing the sources of sediment will have a positive effect on water quality as it relates to turbidity and sedimentation within the channel.

No change is expected in dissolved oxygen levels as they relate to treatments, since any newly created slash would be removed from stream courses within 48 hours after deposition. Thinning RHCAs adjacent to low velocity streams may actually improve oxygen levels by decreasing nutrient overloading from materials decaying in place. All of the streams within the Freeman DFPZ are low velocity. In streams, the consumption of organic matter by bacterial requires oxygen. The amount of oxygen required for bacterial decomposition is the biochemical oxygen demand (BOD), a commonly used measure of water quality. When consumption by bacteria is high, oxygen levels in the water are reduced. When oxygen levels are too low fish and other organisms die.

Where RHCAs would be mechanically treated, ground based equipment would only be used on slopes less than or equal to 15% and on stable soils. Aspen units in RHCAs in Alternative 3 and 4 would have slope restrictions of less than or equal to 35 %. RHCAs with sensitive areas (e.g., springs, bogs, erosive soils, etc.) would not be entered with ground-based equipment. All mechanical equipment would be excluded from within 100 feet (horizontal) of fish baring streams, 50 feet of perennial streams, 25 feet from intermittent and ephemeral streams and 25 feet from all non-fish baring streams within aspen units. These streamside zones would serve as effective filter and absorptive zones for sediment originating from upslope treatment areas. Removal of vegetation within these equipment exclusion zones would be allowed and, would be determined on a site-by-site case to protect the sensitive attributes associated with the riparian area.

No ignition of prescribed fire would occur within 50 horizontal feet of all streams; however, backing fire would be allowed into these areas. Short-term sediment delivery to streams may occur after burning. However, scorched conifers often drop needles following low or moderate severity fires. This needle cast provides ground cover that can help reduce rill and interrill erosion and sediment delivery (Pannkuk and Robichaud 2003). Despite the risk of erosion, the greater long-term benefit of treating these RHCAs is the potential protection from catastrophic wildfire.

Sediment may be reduced due to proposed road activities. Ten miles of roads are proposed for decommissioning. This action would allow vegetative recovery, which can decrease compaction, increase infiltration into the roadbed, increase soil stability and limit concentrated flow as well as surface erosion derived from temporary roads. All temporary roads would be decommissioned after use.

Retention of larger fuels, forest floor cover and deciduous hardwood trees would help maintain the nutrient reservoir stored in organic material.

2) Maintain or restore the stream channel integrity, channel processes and sediment regime under which the riparian and aquatic ecosystems developed. Elements of the sediment regime include the timing, volume and character of sediment input and transport.

In addition to reducing the risk for high-intensity fires, thinning of the RHCA will allow the ecosystem within this corridor to return to a more stable historic condition. Historically woody debris was a combination of large and intermediate logs. Debris jams; especially logjams of small material will alter the natural sediment regime. Small material decays at a faster rate; entrainment of sediments is short term as decaying logs fail. During peak events small material cannot hold sediment in place. Released sediment will affect timing, volume and character of the input. End cutting and scouring within the channel caused by heavy loading of dead and downed material will influence the timing, volume and character of sediment being transported through the system.

Ground disturbance by equipment would be limited because only slopes less than or equal to 15% would be entered with ground-based equipment, except in Aspen units which would be less than or equal to 35% under Alternative 3 and 4. Retention and concentration of large diameter snags within RHCAs would occur. There may be short-term erosion from management activities, as discussed above, with a longer-term reduction in the risk of catastrophic wildfire. Ten miles of roads are proposed for decommissioning/closing, which would reduce erosion into the aquatic system. The green-line characteristics would not be compromised and thus stream channel integrity would be maintained.

3) Maintain or restore in-stream flow to support desired riparian and aquatic habitats, the stability and effective function of stream channels and the ability to route flood discharges.

Thinning of the RHCAs will reduce transpiration and interception. If transpiration is reduced, then runoff and groundwater infiltration could increase. Also interception of rain, snow and the subsequent evaporation effects water availability. Reduction of the canopy cover and removal of conifers throughout the RHCA will initially reduce the interception of precipitation and possibly provide more water to meadows and wetlands. Runoff may increase in the short term. This additional water may increase baseflow to perennial streams and extend intermittent stream flow further into late spring or early summer.

The main objective is to reduce the potential for catastrophic wildfire and thus retain the RHCA's desired riparian and aquatic habitats, effective stream channel function and the ability to route flood discharges. In-stream flows would be assessed during equipment operations, with respect to drafting requirements.

Within RHCAs, the green line would be preserved and remain unaffected by harvest activities. Within the immediate riparian areas the physical effects derived from in-channel large woody debris (LWD) would be sustained, as no natural in-channel debris would be removed. Future recruitment of LWD would be encouraged through release of the existing conifers and the snag retention standards for channel morphology, channel function and bank stability.

Most streams within the project area flow into Lake Davis where they become part of the water the feeds the state water project. Water is subsequently released from the reservoir and made available for downstream beneficial use. The effect of water diversion on future instream flow is beyond the scope of this project.

4) Maintain or restore the natural timing and variability of the water table in meadows and wetlands.

Plants are continuously pumping water from the ground to the atmosphere through a process called transpiration. Transpiration is a function of the density, root mass and size of that vegetation. If transpiration is reduced, then runoff and groundwater infiltration could increase. Also interception of rain, snow and the subsequent evaporation effects water availability. Reduction of the canopy cover and removal of conifers throughout the RHCA will provide more water to meadows and wetlands. This additional water will increase baseflow to perennial streams and extend intermittent stream flow further into late spring or early summer.

Activities proposed in the project area are not expected to maintain or improve the timing and variability of water tables within meadows and wetlands. All sensitive riparian areas (springs, bogs, wetlands and meadows) would be protected by the SAT guideline buffers and the implementation of BMPs. Wet meadows and green-lines would not be entered. Ground based equipment would only be allowed on stable soils, slopes less than or equal to 15% and non-sensitive locations.

5) Maintain or restore the diversity and productive nature of native and desired non-native plant communities in the riparian zone.

Thinning of conifers and retention of all hardwood species within RHCAs would reduce competition and improve diversity. Within the RHCAs aspen would be released to promote aspen health.

6) Maintain or restore riparian vegetation to provide an amount and distribution of large woody debris characteristics of natural aquatic riparian ecosystems.

Large woody material adds structure to stream channels and creates fish habitat. It also provides habitat for small burrowing mammals and acts as a reservoir, retaining moisture throughout the summer months. This moisture is used by a host of organisms. Another benefit of large woody material is it provides nutrients to the ecosystem over the long term.

Thinning of the RHCAs will return the project area to a level of stocking and health that is more closely related to its natural condition. While biomass volume may be near historic levels, we must recognize that instead of being in the boles of a few large trees it is in numerous small, less fire resistant trees. Removing the ladder fuels will encourage the stand to return to its natural state and greatly enhanced it by reducing competition for nutrients, water and sunlight.

Within treatment units, the objective is to reduce the concentrations of fine fuels. Where down logs exist, 10-15 tons per acre of the largest down logs having diameters greater than 12 inches would be retained. There would be minimal burning of LWD logs greater than 12 inches dbh. Thinning within RHCAs may release the residual conifers and deciduous trees to increase diameter growth. LWD retention standards would be implemented. Potential recruitment of LWD into the stream channel would be retained and enhanced. There would be a reduction in potential catastrophic wildfire and therefore a greater potential of LWD retention. Back burning would occur during times where there is increased moisture, resulting in less LWD consumption. Also, the prescription is to consume the fine fuels- residual fine fuel (less than 3 inches in diameter) would not exceed 5 tons per acre.

7) Maintain or restore habitat to support populations of well-distributed native and desired non-native plant, vertebrate and invertebrate populations that contribute to the viability of riparian plant communities.

Living plants provide erosion control, shade and their root systems create macro-pores increasing infiltration rates. The decomposition of plants and contributes to soil matter and composition, provides nutrients and water storage. During thinning of the RHCAs measures will be applied to insure ground cover levels are maintained and vegetation providing stability to channel banks is not removed. Riparian zones (specifically the green line), springs, seeps and bogs would be identified and protected from harvest activities. Impacts would further be reduced by the application of BMPs and standard management requirements.

Vertebrates that influence the viability of riparian plant communities include pocket gophers, moles, butterflies, bats and ground squirrels. Thinning of the RHCAs will have no detrimental effect on these species, thus their populations will continue to maintain the viability of riparian plant communities.

Invertebrates contribute to the viability of riparian plant communities in many ways. They act as decomposers, shredding dead plant materials and they burrow into woody debris. Invertebrates recycle nutrients and influence soil structure. They improve soil porosity and improve oxygen-penetrating capabilities. To maintain invertebrate populations, compaction will be minimized and ground cover disturbance will be minimized through the use of low ground pressure equipment, hand treatments methods and sub-soiling of skid trails.

8) Maintain or restore riparian vegetation to provide adequate summer and winter thermal regulation within the riparian and aquatic zones.

Summer and winter thermal regulation within the riparian and aquatic zones would be maintained. Trees shading stream channels would not be harvested and canopy cover within the RHCAs would be maintained at 40 percent and would not be reduced below 60 percent along any fish-baring stream. Activities proposed in the project area are not expected to negatively impact riparian vegetation. Group selection harvest would only occur outside of RHCAs.

9) Maintain or restore vegetation to help achieve rates of surface erosion, bank erosion and channel migration characteristics of those under which the desired communities developed.

Riparian vegetation will be protected and maintained while coniferous ladder fuels are thinned. Except at designated crossing stream banks will not be impacted by equipment and it is not expected bank erosion will be accelerated either by equipment or by the implementation of the project.

Thinning RHCA will promote diversity and increase production of riparian communities. Burning of isolated handthin piles will remove groundcover at point locations but soil moving from these points will be trapped by ground cover immediately adjacent to the hand piles.

The maximum erosion hazard for soil types within the project area, ranging from low to very high, suggests that channel development has occurred under significant sediment loads. The riparian green line of stream channels would not be impacted by the proposed management activities and natural recovery processes within the streamside area would help moderate stream temperatures. Riparian vegetation may increase in vigor due to increased water yield and reduced competition by conifers through thinning in the RHCAs. Within the immediate riparian areas, the physical effects derived from in-channel LWD would be retained, as no natural debris would be removed. Future recruitment of LWD, which is structurally important for channel morphology, channel function and bank stability, would be encouraged through snag retention requirements and release of existing live conifers.

10) Maintain and restore riparian and aquatic habitats necessary to foster the unique genetic fish stocks that evolved within the specific geo-climatic ecoregion.

Maintenance of the riparian habitat necessary to foster unique genetic fish stocks will be accomplished by prescribing treatment that will maintain bank stability, ground cover and restrict erosion. In the all action alternatives no mechanical treatment will occur in the first 100 feet of all fish bearing streams.

Short term increase in sediment yields during storm events within the analysis area could reduce available gravels for spawning and, to a minor degree, may alter the composition of aquatic invertebrates in Freeman, Cow and Dan Blough Creeks but it is expected that any change would be minimal and not measurable. It is expected that water temperatures in the intermittent and perennial streams early in the summer would not be affected by project activities, since vegetative shading would not be reduced to detrimental levels within the RHCA's.

It is expected that the alternatives would not have a substantial impact on the fish populations in Freeman, Cow and Dan Blough Creeks. The best opportunity to improve channel conditions and fishery habitat along these streams is through the decommissioning and relocation of roads adjacent to stream channels, stream channel restoration and improved grazing strategies along streams

CONDITIONS

The Permittee shall, in addition to all of the conditions detailed on the back of this form, take the following precautions:

Any person who violates Northern Sierra Air Quality Management District Rules and Regulations is guilty of a misdemeanor punishable by imprisonment in the County Jail not exceeding 12 months and/or a fifty thousand dollar ($50,000) fine. The cost of putting out any unauthorized open outdoor fire may be imposed on any person when applicable. I have read and fully understand the conditions of this permit. I understand I could be liable in the event the fire creates a nuisance, a hazard or escapes control. I also understand noncompliance with the conditions of this permit may result in the assessment of penalties pursuant to the California Health & Safety Code §42400 et seq.

The permittee is responsible for complying with all of the following conditions:

1. This permit is valid only on "Burn Days" as designated by the State Air Resources Board or the Air Pollution Control Officer.
2. The material to be burned shall meet District requirements for minimum drying times. Specifically, 3 weeks minimum for all material and 6 weeks for trees, stumps, and branches greater than 6 inches in diameter.
3. The use of tires for ignition of fires is prohibited.
4. The material to be burned shall be arranged to facilitate efficient burning and shall be free of waste such as tires, rubbish, tar paper, construction debris, and excessive amounts of soil or moist materials.
5. All open outdoor fires shall comply with applicable Local, County, and State regulations.
6. This permit is valid only for the location as specified in the "Location of Burning Site" field on the front of this permit.
7. This permit or a copy thereof shall be available at the burn site for review by any Air District personnel upon request.
8. A responsible party must be in attendance and control of burn at all times.
9. This permit may be revoked or suspended for violation of any conditions of this permit or when it is necessary for public safety.
10. All burns shall be hot, clean and have little to no smoke impact on surrounding residents.
11. Only those burn piles that can reasonably be expected to completely burn within the following 24 hours shall be ignited in any one day.
12. The permittee agrees to extinguish any and all of his burn piles upon the request of any Air District personnel or any Fire Agency personnel.

Pursuant to the California Health and Safety Code §42409, the Northern Sierra Air Quality Management District is publishing and making available a list of potential violations subject to penalties that may be assessed by the District. Additional violations and penalties are as specified in the California Health & Safety Code.

Health & Safety Code §42400 provides (except as outlined in subsequent sections) that any person who violates any provision of Health & Safety Code Part 3, or any order, permit, rule or regulation of the state board, or the District, including the District Hearing Board, is guilty of a misdemeanor and is subject to a fine of up to $1,000 per day or imprisonment in the county jail for not more than 6 months, or both.

Health & Safety Code §42400.1 provides that any person who negligently emits an air contaminant in violation of any rule, regulation or order of the state board or of the District pertaining to emission regulations or limitations is guilty of a misdemeanor and is subject to a fine of up to $25,000 per day, or imprisonment in the county jail for not more than 9 months, or both, with more severe penalties in the case of great bodily injury or death.

Health & Safety §42400.2 provides that any person who emits an air contaminant in violation of any provision of the Health & Safety Code Part 3, or any order, rule or regulation of the state board or the District pertaining to emission regulations or limitations, and who knew of the emission and failed to take corrective action within a reasonable period of time under the circumstances, is guilty of a misdemeanor and is subject to a fine of up to $40,000 per day, or imprisonment in the county jail for not more than one year, or both.

More severe penalties than those listed above may be applied to willful or intentional violations.

A person who owns or operates any source of air contaminants in violation of §41700, Public Nuisance, which causes actual injury to the health and safety of a considerable number persons or the public, is liable for a civil penalty of not more than $15,000. Each day on which a violation occurs is a separate offense.

The recovery of civil penalties pursuant to Health & Safety Code §42402 *et seq.* precludes prosecution for the same offense. When the District refers a violation to a prosecuting agency, e.g. District Attorney, the filing of a criminal complaint requires the dismissal of any civil action for the same offense.

In addition to any civil or criminal penalties prescribed under Health & Safety Code Part 3, the Northern Sierra Air Quality Management District may impose administrative civil penalties (§42402.5), not to exceed $500 for each violation of State or District rules and regulations.

NEPA Status

Categorical Exclusion

Submit the signed, approved Decision Memo and Categorical Exclusion, as well as documentation to support the Categorical Exclusion, including any permits, surveys, and/or reports that have been completed to support this NEPA status.

All NEPA documentation can be found in the NEPA folder on the compact disk that accompanies this application.

Environmental Assessment & Finding of No Significant Impact

Submit the signed, approved Environmental Assessment and Finding of No Significant Impact along with any permits, surveys, and/or reports that have been completed to support this NEPA status.

All NEPA documentation can be found in the NEPA folder on the compact disk that accompanies this application.

Environmental Impact Statement

Submit the Draft and approved, Final Environmental Impact Statement, along with the Record of Decision and any permits, surveys, and/or reports that have been completed to support this NEPA status.

All NEPA documentation can be found in the NEPA folder on the compact disk that accompanies this application.

Decision Notice and Finding of No Significant Impact

for

Ingalls Project Environmental Assessment

USDA Forest Service, Plumas National Forest
Beckwourth Ranger District

Plumas County, California

Location

The Ingalls project area covers 17,909 acres of the Beckwourth Ranger District on the Plumas National Forest. The project area is located northwest of Lake Davis. It is within all or parts of T25 N, R.12 E, Sections 13, 22-28, 33-36, T25 N, R13 E, Sections 30-33, T24 N, R12 E, Sections 1-3, 11-16, and 21-24, T24N, R13E, Sections 3-10, 14-27.

Decision

I have read the Ingalls Project Environmental Assessment (EA), reviewed the analysis in the project record, including documents incorporated by reference, and fully understand the environmental effects disclosed therein. Based upon my review of all the alternatives and the comments received from the public for this project, I have decided to implement Alternative 1. Alternative 1 is described fully in Chapter 2 of the Ingalls Project EA (pages 23-29).

This decision will treat approximately 3,401 acres within defensible fuel profile zone (DFPZ) units, 599 acres within area thin units, 95 acres within aspen units (Table 1) and approximately 44 acres of group selections that fall within mechanical thinning units. This decision will implement the following road treatments: decommission/obliteration (4.8 miles), reconstruction (14 miles) and construction/obliteration of temporary roads (8.4 miles).

Table 1. Summary of actions and acres treated in the Ingalls Project area.

Actions	Acres (approximate)
DFPZ	
Mechanical thinning	1,231
Mastication	166
Grapple pile with hand thin	110
Hand thin with underburn	780
Underburn	343
No treatment	771
Total DFPZ	3,401
Area thin	
Mechanical thinning	599
Total area thin	599
Aspen/cottonwood thin	
Mechanical thinning	95
Total aspen/cottonwood thin	95
Grand Total	**4,095**

Decision Rationale

I considered a number of different criteria when deciding which alternative to select. No single factor or concern entirely prevailed in determining my choice of alternative selection, although certain purpose and need criteria did not differ greatly among alternatives so were not as important when making my decision. The criteria I focused on, because they did differ across alternatives, were the purpose and need criteria related to forest health and fire resiliency, old forest emphasis habitat and associated wildlife species, aspen and cottonwood growing conditions and criteria related to effects to wildlife and hydrology.

I believe Alternative 1 provides a balance in terms of meeting the purpose and need without excessive effects to other resources. Alternative 1 is designed based on recommendations made through group discussions conducted during field visits to the Ingalls Project that centered on creating a healthy fire resilient forest while addressing wildlife concerns, aspen and cottonwood treatments and group selection treatments with interested members of the public. Alternative 1 also addresses off road vehicle (OHV) users concerns regarding road decommissioning.

Overall, my principal aim is the clear need to protect the basic resources, primarily soil, water, wildlife and vegetation from not only the predicted effects of our proposed activities, but also from the potential effects of wildfire. The emphasis on management actions designed to reduce the adverse effects of wildfire in California and throughout the west is emphasized by both national policy and direction. I am all too familiar with the tremendous resource damage and restoration challenges in the aftermath of major wildfires. Any action large enough to truly make a change in the trend of landscape forest conditions will inherently have some short-term and perhaps long-term risks. In the case of this project, I believe the risks have been identified, analyzed and effectively mitigated. I must balance predicted risks and expected benefits. I have decided that on this project the risks are reasonably predictable and can be effectively mitigated. Similarly, the risks associated with wildfire are apparent to me, and that many of the resource impacts caused by wildfire are not easily mitigated or repaired.

Ecological Restoration

In Region 5 of the US Forest Service, the goal of ecological restoration is to retain and establish ecological resilience of lands to achieve sustainable management on our wildlands and forests and to provide for ecologically healthy and resilient landscapes. The goal of ecological restoration is important to me. I believe the activities included in this decision work toward meeting both the project purpose and need and the larger Region 5 goal of ecological restoration. Achieving the purpose and need has been met by working with interested parties using "An Ecosystem Management Strategy for Sierran Mixed-Conifer Forests" (PSW-GTR-220, 2009) as a basis for the design features where consistent with direction in the 1988 LRMP as amended by the 1999 HFQLG ROD and the 2004 SNFPA ROD. The District met with interested parties multiple times throughout the design process. Through this collaboration process the interdisciplinary team incorporated new project design criteria that address ecological restoration across the landscape while creating an effective

DFPZ. The District also collaborated with OHV users to maintain existing opportunities to dispersed camping while mitigating resource needs.

Achievement of Purpose and Need

Strategically Reduce Fuel Loads

This decision will change fire behavior within the DFPZ, increasing our ability to manage fires within the Ingalls Project area. The activities will move the existing conditions toward the desired fuel conditions in areas treated by reducing surface fuels and ladder fuels, raising canopy base heights, and reducing canopy fuels. Fuel reduction treatments will create conditions conducive to reintroducing periodic low-intensity prescribed fire. During 90th percentile weather conditions, implementation of this decision will have raised canopy base height from 6.7 feet to 16.6 feet, reduced expected flame lengths from 9.9 to less than one foot, reduced surface fuels from 20 tons/acre to less than six tons/acre, and reduced expected conifer mortality from 98 percent to less than 10 percent (Ingalls Project EA, page 33).

Implementation of these actions will provide safer locations for firefighters to suppress wildland fire. Implementation of fuel treatments will decrease the risk of fire spread by modifying fire behavior and enhancing the ability of the firefighters to contain, suppress, and control wildfires within and adjacent to the treatment areas (Ingalls Project EA pages 46-52). The treatments within the project area will strategically connect already planned and implemented DFPZs (Freeman, Grizz and Red Clover DFPZs) on National Forest System lands, and further the completion of a DFPZ network on the Beckwourth Ranger District.

Improve Forest Health and Fire Resiliency

This decision will increase stand vigor by reducing competition for limited resources within overly-dense forest stands. Treatments will create a more complex stand structure which focuses on creating variation within and across stands. Activities will be focused on creating structural diversity (varying tree age and size) within stands and across the landscape that provides a variety of wildlife habitat elements, while creating fire-resilient stands. A percentage of smaller trees will be left for diversity, structure, and to provide for the next generation of forest. Preferences for removal of shade tolerant trees that have grown in the absence of frequent fires will provide for a more sustainable species composition. Tree density (basal area and stand density index) will be reduced to a level where stand and tree health will be improved and project activities will move stands toward desired tree species composition and structure (Ingalls Project EA, pages 74-87). By improving forest the risk of high levels of insect-related mortality already seen in the majority of the stands in the Lake Davis area will be reduced.

Provide for Old Forest Ecosystems and Associated Wildlife Species

This decision will focus on promoting old forest ecosystem habitat components for associated wildlife species. Area thin stands within the Ingalls project area are comprised primarily of dense even-aged trees, which do not provide old forest ecosystem habitat components and are at risk of loss to disease/insect infestation. Treatments will focus on promoting structural complexity and improving stand health in order to produce large diameter fire-resilient trees in the future. In general, there will be a small percent reduction in old forest emphasis habitat components in the short term (Ingalls Project EA pages 33-34). However, in the long term treatments are designed to promote large tree growth and structural diversity. Wildlife diversity patches will be located in areas that provide habitat elements for old forest ecosystem wildlife species. In addition, by treating fuels within these stands the risk of losing valuable habitat to wildfire will be reduced.

Improve Aspen and Cottonwood Growing Conditions

This decision will improve aspen and cottonwood growing conditions by removing conifers from aspen and cottonwood stands, thereby increasing light availability and providing the proper growth environment for young aspen and cottonwood. Risk to aspen and cottonwood stands will be lower, overall health of these stands is expected to improve, and conditions for aspen and cottonwood regeneration will be improved (Ingalls Project EA, page 34).

Contribute to the Economic Health and Stability of Local Rural Communities

This decision will provide jobs to the local community and timber products for the local mills. Plumas County's geographic location has historically isolated it from urban job markets. Its reliance on jobs in the woods ties much of the local economy to the proper management of natural resources. The decrease of logging since the mid-1980's has caused the number of sawmills within the area to dwindle from six to one, which is located in Quincy. Alternative 1 is estimated to provide 165 full-time jobs, produce approximately 7.4 million board feet (mmbf) of sawlog volume and generate roughly $6,591,000 in employee-related income (Ingalls Project EA, page 34).

Provide Road Access to Meet Project Objectives while Reducing Transportation System Effects

This decision will reduce transportation system effects within the project area. This decision will decommission segments of existing roads currently causing resource damage, and will help reduce road density, reduce sediment derived from concentrated flow associated with the roads, and enhance infiltration. Activities would improve 14 miles of roads and restore 0.6 acres of hydrologic function (Ingalls Project EA, page 34).

Effects to Other Resources

Alternative 1 will implement a diversity of treatments to modify fire behavior on the landscape as well as improve forest health and fire resiliency, while reducing environmental impacts associated to wildlife and hydrology. Alternative 1 is expected to reduce nesting and foraging habitat of California spotted owl and Northern goshawk (Ingalls Project EA page 34). While there may be short term impacts to these species, treatment designs that enhance structural complexity should provide long term benefits as well as reduced risk of loss due to wildfire. In addition, certain watersheds are over threshold due to many different types of activities occurring within the Lake Davis area. However, mitigation measures are in place to protect soil and water resources (Ingalls Project EA page 167-168, 212-216). While I am aware that project activities present some risk to forest resources, I am committed to implementing protection measures described as part of the proposal for this project. These protection measures are expected to minimize and/or prevent damage to forest resources (Ingalls Project EA pages 31-33, 212-220).

Other Alternatives Considered

Two other alternatives were analyzed in detail for the Ingalls Project. These were the no-action alternative (Alternative 2) and the noncommercial funding alternative (Alternative 3), which was developed based on direction in the Memorandum and Order dated November 4, 2009, United States District Court, during the remedy phase in the complaint of Sierra Forest Legacy vs. Mark Rey. The reasons why Alternatives 2 and 3 were not selected are discussed below.

Alternative 2 (No Action)

I did not choose this alternative because it does not meet the purpose and need for action. It would not enhance the ability of fire management personnel to suppress, control, and contain fires within the Ingalls Project area and could impact wildlife species habitat. This alternative would not provide the connectivity to previously implemented DFPZs: Freeman, Grizz and Red Clover. Firefighter safety would not be improved. Under 90th percentile weather conditions, predicted flame lengths would create a situation where direct fireline attack would be precluded and firefighters would have to employ indirect suppression methods. This would allow fires to become larger, more expensive, and potentially more hazardous for firefighters and the public. In addition, loss of wildlife habitat could impact many wildlife species such as California spotted owl, northern goshawk, bald eagle, great gray owl, etc. This alternative would not: increase forest health or stand resilience to fire, provide for old forest emphasis habitat, improve growing conditions within aspen and cottonwood stands, reduce transportation system effects, or contribute to the economic stability of local rural communities.

Alternative 3 (Noncommercial Funding)

Alternative 3 is described fully in Chapter 2 of the Ingalls Project EA (pages 29-31). These treatments include treating approximately 3,401 acres within DFPZ units with a combination of mechanical thinning (1,231 acres), mastication (166 acres), grapple pile with hand thin (110 acres), hand thin with underburn (780 acres), and underburn only (343 acres). A total of 771 acres would receive no treatment because they already meet desired conditions. Area thin and aspen and cottonwood stands would not be treated. Alternative 3 includes the following road treatments: reconstruct (13.3 miles) and new temporary roads (3.9 miles). No roads would be decommissioned.

Alternative 3 includes treatments to address only the purpose and need for reducing hazardous fuels to modify fire behavior. I did not choose this alternative because it would not fully meet the purpose and need for improving forest health and fire resiliency and improving old forest emphasis habitat. This alternative would not provide the structural diversity of Alternative 1 because it would remove the majority of trees in the understory leaving an evenly spaced stand with trees that are similar in age and size. The resultant stand would not have the characteristics needed for old forest emphasis associated wildlife species. This alternative would not improve growing conditions within aspen and cottonwood stands or reduce transportation system effects because thinning in aspen and cottonwood stands and road decommissioning would not occur in this alternative. Although this alternative could contribute to economic activity within local communities (117 jobs created), this alternative would not achieve the purpose and need of contributing to the stability of local rural communities as well as the selected alternative (165 jobs created) because sawlog volume is greatly reduced in Alternative 3 (1.1 mmbf) compared to Alternative 1 (7.4 mmbf) (Ingalls EA page 96).

Additionally, the ability of the Plumas National Forest (Forest) to fully implement this alternative is questionable. It is important to note that both of the action alternatives would need additional funding to be fully implemented; however, whereas the value of commercial sized material removed through thinning would offset/reduce the cost of implementing most of Alternative 1, the economic value of Alternative 3 is so low that appropriated dollars or grants would be needed to accomplish the work. As more work becomes contingent on these funds, the likelihood of accomplishing proposed activities is greatly reduced. In part my decision not to choose this alternative was based on the lack of certainty that effective treatments could be accomplished within a desirable timeframe.

Conclusion

The focus of Alternative 1 is to implement a diversity of treatments to modify fire behavior on the landscape as well as improve forest health and fire resiliency, while reducing environmental impacts to associated old forest emphasis wildlife species and hydrology. Alternative 1 was designed to provide for old forest ecosystem characteristics by promoting structural complexity across the landscape by incorporating a more restorative thinning prescription. In addition, Alternative 1 improves aspen and cottonwood growing conditions and reduces transportation system impacts. In contrast, Alternative 3 is a thin from below thinning prescription which removes the majority of trees in the understory with an even spacing. This treatment type traditionally does not provide for the structural complexity that many species such as the California spotted owl and northern goshawk need. Alternative 3 would also not treat aspen and cottonwood stands or reduce transportation system effects.

Public Involvement

The "Ingalls Project" first appeared in the Plumas National Forest quarterly Schedule of Proposed Actions (SOPA) in the 4th quarter, 2009. As required in the Healthy Forest Restoration Act (HFRA) process, the District held a public meeting on November 12, 2009. An announcement was published in the *Feather River Bulletin* and *Portola Reporter* two weeks in advance of the meeting. No comments were received. The District facilitated public collaboration among State and local governments, tribes, and interested persons as follows. The District gave a presentation to the Plumas Fire Safe Council on June 12, 2008 prior to finalizing the Proposed Action, purpose and need. There were two additional group field meetings held with members of Sierra Forest Legacy and Quincy Library Group.

The District started the HFRA (36 CFR 218) public comment process and NEPA scoping process with publication in the *Feather River Bulletin* (and *Portola Reporter*) on May 12, 2010. A detailed scoping letter outlining general existing conditions, proposed treatments, and acres planned for treatments was mailed to 18 individuals, organizations, and government entities. A total of four comment letters were received. The Ingalls project file contains public letters, records of phone calls and visits to the area, mailing lists, and other documentation of the outreach and discussions held with members of the public.

Representatives from the Quincy Library Group, Sierra Forest Legacy, Sierra Pacific Industries and Natural Resource Conservation Service attended an additional public field trip to the Ingalls project area on September 22, 2010. The design of Alternative 1 was a direct result of recommendations made through discussions conducted during field visits to the Ingalls Project that centered on variable density thinning treatments, wildlife concerns, group selection treatments and road decommissioning.

Finding of No Significant Impact

In finding that the Ingalls Project has no significant impact, I looked at the project's effects, both in context and in intensity. I have looked at the action in several contexts such as the affected region, affected interests and the locality. I have addressed the intensity of the project and the extent of its impact. Taking both into consideration, I have determined that there are no significant impacts based upon the following:

a) Context:

The local context of this action is limited to the southeastern portion of the Plumas National Forest, in locations described on pages 11 and 12 of the EA. Proposed treatments focus on reducing surface, ladder, and canopy fuels in order to modify fire behavior, thus reducing fire intensity and fire severity as well as improving forest health by decreasing stand density (trees/acre), improving tree health, growth rates and ability to combat insects and disease by retaining the healthiest fire-resilient trees (Ingalls Project EA, pages 12-14).

The Ingalls Project is part of the larger Herger-Feinstein Quincy Library Group (HFQLG) Forest Recovery Act Pilot Project. The law that authorizes this pilot project was passed by Congress and signed into law by the President in October of 1998. An EIS was completed for this pilot project in 1999, and was supplemented in 2003. The Act limits total acreage affected by resource management activities to about 70,000 acres annually in the pilot project area. The 4,095 acres of treatments proposed for the Ingalls Project, will constitute approximately six percent of the total annual acreage of management activities under HFQLG. For that reason, the scale of the Ingalls Project is not indicative of significant effects, even when considered in terms of local effects within the pilot project area, and even when considered in terms of only one year's program of activities under the pilot project.

b) Intensity:

1) Impacts both beneficial and adverse.

Effects determinations are summarized in the Ingalls Project EA (pages 33-34) and supporting analysis. Both beneficial and adverse effects have been taken into consideration when making the determination of significance. Beneficial effects have not, however, been used to offset or compensate for potential significant adverse effects.

2) The degree to which the proposed action affects public health or safety.

There will be no significant effects on public health and safety because of project specific design features and mitigations and the implementation of standard operating procedures (Ingalls Project EA, pages 194-197, 216).

Access and harvest operations will involve use of mechanical equipment; falling of trees; hauling of harvest products on National Forest System (NFS) roads, county roads, and state highways; and use of prescribed fire, all of which potentially pose risks to workers and to the public. Such risks will be reduced because the public will be alerted to active harvest areas, and haul routes on NFS roads will be clearly signed and monitored as required in contract provisions to warn and protect the public of project activities. Roads within the project area may be closed to the recreating public on a temporary basis for safety reasons. These closures are of limited duration. (Timber Sale Contract Provisions)

The project area lies within the Northern Sierra Air Quality Management District (NSAQMD). In accordance with Title 17 of the California Code of Regulations, a smoke management plan will be submitted to and approved by the NSAQMD prior to any prescribed fire ignitions that are part of this alternative. With adherence to the burn plan including a mandatory smoke management plan (SMP), daily coordination among local fire management officials (Air Quality Management Districts, the California Air Resources Board, the Geographical Area Coordination Center meteorologists and agencies that are conducting prescribed fire operations) and Air Quality Management District requirements for burning and managing other project activities, it is unlikely that emissions caused by the project would exceed California Air Quality Standards for the Air Quality Management District (Ingalls Project EA, pages 55-60, 212).

Fugitive dust from operations will be mitigated by standard operating procedures and contract requirements for road watering or other dust abatement techniques (Ingalls Project EA, page 216).

3) Unique characteristics of the geographic area, such as proximity to historic or cultural resources, park lands, prime farmlands, wetlands, wild and scenic rivers, or ecologically critical areas.

There are no parklands, prime farmlands, wild and scenic rivers, or ecologically critical areas within the project area.

The Ingalls Project provides protection to wetlands by implementing Best Management Practices (BMPs). By using BMPs, the Ingalls Project meets the executive orders according to the 2004 Sierra Nevada Framework Forest Plan Amendment Record of Decision (Ingalls EA, page 212-215).

The Ingalls Project will have no significant effect to historic or cultural resources (see #8 below).

4) **The degree to which the effects on the quality of the human environment are likely to be highly controversial.**

The effects on the quality of the human environment are not likely to be highly controversial. Based on comments received during the public involvement process, there is no substantive scientific controversy related to the effects of the proposed treatments on the human environment (Ingalls Project EA, pages 20-21).

5) **Degree to which the possible effects on the human environment are highly uncertain or involve unique or unknown risks.**

The Forest Service has considerable experience implementing the activities in this project. The possible effects of implementing Alternative 1 are neither highly uncertain nor will they present unique or unknown risks. The consequences of these actions are known, as described in each specialist report (Ingalls Project record and summarized in the Ingalls Project EA, pages 33-36).

6) **The degree to which the action may establish a precedent for future actions with significant effects, or represents a decision in principle about a future consideration.**

The Ingalls Project is site-specific and the implementation of this decision will not establish a precedent for future actions with significant effects or represent a decision in principle about a future consideration. Any additional resource projects within or adjacent to the project area will require a separate environmental analysis at that time.

7) **Whether the action is related to other actions with individually insignificant but cumulatively significant impacts.**

This decision does not represent potential significant cumulative adverse impacts when considered in combination with other past, ongoing, or reasonably foreseeable future actions.

A cumulative effects analysis was completed separately for each resource area. The geographic scope of the cumulative effects analysis area varied among resource areas (Ingalls Project EA, pages 38-40, 46-54, 57-60, 72-73, 85-87, 92, 95-97, 105-108, 110, 117-120, 124, 126, 128-136, 143-148, 164, 167-169, 176-180, 183-184, 186-189, 193, and 195-197). None of the specialists found the potential for significant adverse cumulative effects. A summary of actions considered in each cumulative effects analysis is contained in Appendix C (Ingalls Project EA, pages 221-224). Future maintenance actions will be analyzed separately and site-specifically, in compliance with NEPA.

8) **The degree to which the action may adversely affect districts, sites, highways, structures, or objects listed , or eligible for listing, in the National Register of Historic Places or may cause loss or destruction of significant scientific, cultural, or historical resources.**

This action will have no significant adverse effect on districts, sites, highways, structures, or objects listed in or eligible for listing in the National Register of Historic Places, or cause the loss or destruction of significant scientific, cultural, or historic properties (Ingalls Project EA, page 193).

9) **The degree to which the action may adversely affect an endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973.**

This action will not adversely affect any endangered or threatened species or its habitat that has been determined to be critical under the Endangered Species Act of 1973 because no federally listed terrestrial, or aquatic wildlife, or botanical species exists within or adjacent to the project area, (Ingalls Project EA, pages 198-199).

10) **Whether the action threatens a violation of Federal, State, or local law or requirement imposed for the protection of the environment.**

The action will not violate Federal, State, and local laws or requirements for the protection of the environment (Ingalls Project EA, pages 238-243).

Findings Required by Other Laws and Regulations

This project was proposed according to management direction provided by the 1988 Plumas National Forest Land and Resource Management Plan (LRMP) as amended by the Herger-Feinstein Quincy Library Group Forest Recovery Act (HFQLG FRA) 1999 Final Environmental Impact Statement and Record of Decision (ROD), the 2003 HFQLG FRA Supplemental EIS and ROD and the 2004 Sierra Nevada Forest Plan Amendment (SNFPA) Supplemental EIS and ROD (USFS PNF 1988, USFS 1999, USFS 2003, USDA Forest Service 2004). The 2004 SNFPA required that land allocations and application of Standards and Guidelines embodied in the HFQLG ROD be preserved for the life of the pilot project. Planning for this project also involves the use of the Pre-decisional Administrative Review Processes (36 CFR 218) under the authority of the 2003 Healthy Forest Restoration Act (HFRA).

In addition to the FONSI, I find that this project is consistent with the Land and Resource Management Plan for the Plumas National Forest (1988) as amended by the HFQLG Act and the 1999 FEIS ROD and 2003 FSEIS ROD and the 2004 SNFPA ROD. Therefore, this project is consistent with the requirements of the National Forest Management Act of 1976. In addition, the Ingalls Project complies with the Endangered Species Act, and the Clean Water Act (Ingalls Project EA, pages 198-199), and other federal, state, and local laws or requirements imposed for the protection of the environment.

Implementation

Implementation of the decision may occur immediately.

Administrative Review

This project is part of the Herger-Feinstein Quincy Library Group Forest Recovery Act Pilot Project and is being done under the Healthy Forest Restoration Act (HFRA) authority. Therefore, this project decision is not subject to appeal pursuant to 36 CFR Part 215. A 30-day pre-decisional objection period was provided pursuant to 36 CFR 218, ending on September 10, 2011.

On September 9, 2011, Sierra Forest Legacy submitted an objection on the Ingalls Project to Kyla Sabo. This objection was dismissed because it was not filed with the Reviewing Officer (Objection Dismissal Letter dated October 11, 2011).

Contact Person

The Ingalls Project EA and supporting documents are available for public review at the Plumas National Forest, Beckwourth Ranger District, 23 Mohawk Dr., PO Box 7, Blairsden, CA 96103, 530-836-2575. For further information on this decision, contact Kyla Sabo (kylasabo@fs.fed.us), Ingalls Project Interdisciplinary Team Leader at 530-836-2575.

Chapter 1. Purpose and Need

Project Description and Location

The USDA Forest Service, Plumas National Forest (PNF), Beckwourth Ranger District (District) proposes activities to promote healthy, diverse, fire-resilient forest structures, provide for old forest ecosystems and associated wildlife species, improve aspen and cottonwood growing conditions, contribute to the economic health and stability of local rural communities in the northern Sierra Nevada, and provide the road access needed to meet project objectives while reducing transportation system effects. The Ingalls Project area is 17,909 acres with proposed treatments occurring on approximately 4,095 acres (includes no treatment areas that currently meet desired conditions for DFPZs). Activities include mechanical thinning, mastication, grapple piling, hand thinning and underburning in DFPZ and Area Thin treatment units. Also proposed are temporary road construction, reconstruction, decommissioning and obliteration. These actions are part of a broader resource management program, under the authority of the 1988 Plumas National Forest Land and Resource Management Plan (LRMP), as amended by the Herger-Feinstein Quincy Library Group Forest Recovery Act (HFQLG FRA) 1999 Final Environmental Impact Statement (FEIS) and Record of Decision (ROD), the 2003 HFQLG FRA Supplemental EIS and ROD and the 2004 Sierra Nevada Forest Plan Amendment (SNFPA) SEIS and ROD (USFS PNF 1988, USFS 1999, USFS 2003, USFS PSW 2004). Planning for this project also involves the use of the Pre-decisional Administrative Review Processes (36 CFR 218) under the authority of the 2003 *Healthy Forest Restoration Act* (HFRA).

Following large-scale fires throughout the northern Sierra Nevada, efforts have increased to manage fuel buildup on the District by reducing fuels and introducing fire back into the forest. The 2004 SNFPA and 1998 HFQLG Act directed the establishment of a Defensible Fuel Profile Zone (DFPZ) network, designed to limit the size of large-scale wildfires on the landscape. This DFPZ network extends across the Plumas and Lassen National Forests and the Sierraville Ranger District on the Tahoe National Forest. This project would construct a DFPZ that connects to three previously planned DFPZs: Grizz, Freeman, and Red Clover (Appendix E-2).

The project area is located northwest of Lake Davis within the Beckwourth Ranger District of the Plumas National Forest, Plumas County; the legal description is T. 25 N, R. 12 E, Sections 13, 22-28, 33-36, T 25 N, R 13 E, Sections 30-33, T 24 N, R 12 E, Sections 1-3, 11-16, and 21-24, T 24N, R13E, Sections 3-10, 14-27: Mount Diablo Meridian (Figure 1).

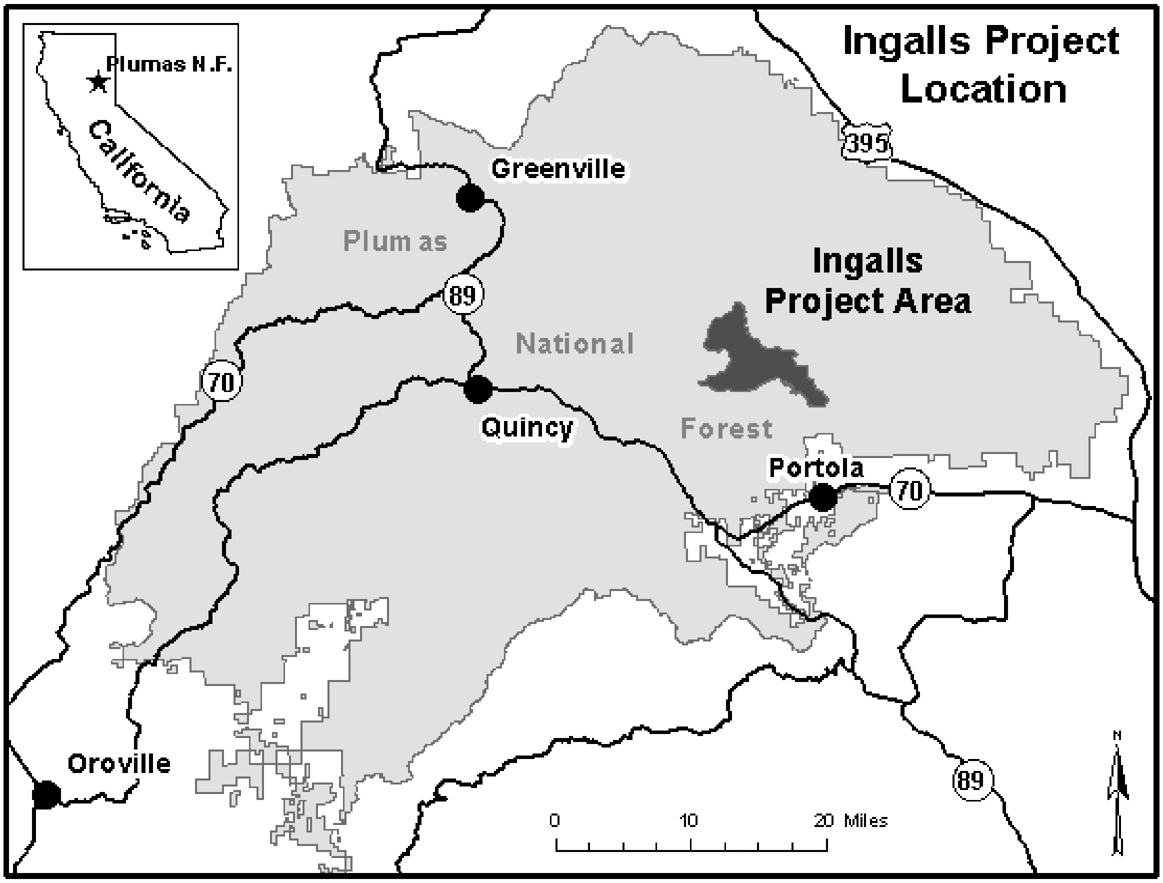

Figure 1. Ingalls Project area within the Beckwourth Ranger District on the Plumas National Forest.

Purpose and Need

Purpose and Need 1: Strategically reduce fuel loads

Objective: Provide connectivity with adjacent DFPZs by modifying surface, ladder and canopy fuels in order to reduce the size, severity and intensity of potential wildfire in the project area, as well as promoting a fire-resilient ecosystem.

Need for Action

The proposed DFPZ locations would provide connectivity to three other DFPZs (Grizz, Freeman and Red Clover) constructing a cohesive network across the landscape. The proposed treatments would modify potential fire behavior by reducing and restructuring surface, ladder and canopy (crown) fuels and promoting a fire-resilient landscape (i.e. open stands, mostly dominated by larger, fire tolerant trees) (Appendix J, HFQLG EIS 1999).

The majority of the Ingalls DFPZ is located on the south facing aspect and ridge top of Turner Ridge near Lake Davis and is in alignment with the prevailing summer wind direction (southwest). This location would provide connectivity to the Grizz and Freeman DFPZs to the west and to the previously implemented Red Clover DFPZ over Bagley Pass in Red Clover Valley. In addition, the location of the Ingalls DFPZ coincides with high recreational use in the Lake Davis area, which has resulted in substantial sources of ignition along County Road 112 and the 28N08 road in the past. Once treated this portion of the DFPZ would provide a safe location for fire fighters to anchor and engage in suppression operations in the event of a fire.

Current forested stand conditions on Turner Ridge consist of moderate to high amounts of surface, ladder and canopy fuels. Existing surface fuel loading across much of the project area would produce flame lengths exceeding the recommended 4-foot flame length. The existing live-crown-base heights are considerably lower than the minimum needed to isolate the tree canopies from surface fire activity. Low crown separation and high tree densities increase the probability of torching of individual trees and subsequent crown fire behavior across stands. The combination of high surface fuel loading, low live-crown-base heights and low crown separation would easily allow a wildfire burning under 90th percentile fire weather to transition from the surface to the forest canopy resulting in rapid large fire growth, moderate to high burn severity and high tree mortality. This would preclude safe, efficient ground based direct attack by wildland firefighters.

Low tree densities and open canopies characterize DFPZ stands located along the base of the slope on County Road 112 on the northeast side of Lake Davis. However, these stands are beginning to experience considerable regeneration and surface fuel build up. In order to maintain DFPZ desired conditions, small diameter trees as well as surface fuels need to be reduced.

Desired Conditions

The desired condition for DFPZ stands would be:

- Reduced surface fuel concentrations to approximately 5 tons per acre (0-1,000 hour fuels (1-4 inches in size)), resulting in shorter flame lengths (< 4 feet); increased fireline production rates for suppression forces, and decreased rate of spread (Appendix J, HFQLG FEIS 1999, 2004 SNFPA ROD).
- Canopy fuels arranged such that the fuel continuity is broken both horizontally and vertically. Horizontal separation of crowns should be sufficient to reduce the potential for crown fire initiation and spread. Vertical separation of the surface and crown fuels, referred to as canopy base height (15-25 feet), would be sufficient to prevent surface fire from igniting the tree crowns subsequently decreasing the likelihood of torching and crown fire initiation (Appendix J, HFQLG FEIS 1999).
- Decreased potential fire intensity and severity thereby decreasing tree mortality (Appendix J, HFQLG FEIS 1999).
- Connectivity achieved with existing DFPZs (Appendix J, HFQLG FSEIS 1999).

Measures of effective fuels reduction include: canopy base height (feet), surface fuels (tons per acre), flame length (feet), percent mortality (%).

Measures of DFPZ connectivity and design placement: topographic placement, road adjacency placement, tie to landscape features (i.e. roads, current vegetation types, rock outcrops), adjacent to planned or existing DFPZs.

Purpose and Need 2: Improve forest health and fire resiliency

Objective: Improve structural diversity and promote the regeneration of shade intolerant and fire resilient tree species to create a healthy, diverse and fire-resilient forest over the project area.

Need for Action

Relative to early historical forest structures, an absence of a natural fire regime and past management practices have left the Ingalls project area with less structural complexity, a greater uniformity in age-classes and an increase in shade-tolerant tree species, such as white fir and incense cedar. Conifer species composition has shifted to favor shade-tolerant species. Fire exclusion has allowed these species to become considerably more abundant and now grow in larger quantities than they did historically, creating dense even-aged stands. These stand conditions can contribute to an increase in competition for limited water, sunlight, and nutrients. Conifers with limited site resources often suffer from a lack of vigor and growth, which can lead to an increase in susceptibility to infestation from insects and diseases, resulting in higher levels than would occur naturally. Currently, DFPZ and Area Thin stands within the Lake Davis Recreation Area are infested with bark beetles and surrounding stands are at high risk to future bark beetle mortality (Cluck 2008). The increase in tree mortality can lead to increasing surface fuel loads, increasing the risk for stand replacement fire.

Desired Conditions

The desired conditions for forest health and fire resiliency would be:

- Increased growth rates by reducing stand densities of intermediate and suppressed trees, leaving residual stands composed of mostly fire-resilient tree species (i.e. ponderosa, Jeffrey and sugar pine, and Douglas-fir).
- Improved forest health by decreasing stand density (trees/acre), by increasing conifer growth rates and ability to combat insects and disease.
- Increased fire resilient tree species regeneration.
- Increased multilayer-canopy and stand size heterogeneity.

Measurement Indicators: Decreased risk of tree mortality (stand density index (SDI), stand basal area (BA), increased tree growth (tree ring width), tree species composition (FVS modeling and trees per acre (TPA) count), tree stand structure (FVS modeling – quadratic mean diameter (QMD), BA, TPA, and canopy cover), insect and disease risk (FVS modeling of risk).

Purpose and Need 3: Provide for old forest ecosystems and associated wildlife species

Objective: Protect, increase and perpetuate old forest ecosystems, habitat components and their associated wildlife species.

Need for Action

Stands in the Ingalls project area (Area Thin units) are comprised primarily of dense even-aged trees, which do not provide old forest ecosystem habitat components and are at risk of loss to disease/insect infestation. Dense stands have little variation in species composition and size, creating homogenous stand structure across the project area. These stands also lack the ability to produce large diameter fire-resilient trees. Stands that do support old forest ecosystem associated wildlife species, such as Northern goshawk, California spotted owl, and great grey owl, are at risk of loss to wildfire, which would result in further fragmenting old forest ecosystem habitat.

Desired Conditions

The desired conditions for old forest ecosystems and associated wildlife species would be:

- Varied stand structure in size and species composition, creating horizontal heterogeneity (2004 SNFPA ROD, pg 41).
- Vertical heterogeneity as a result of multi-tiered canopies consisting of sizes from seedlings to very large diameter trees (2004 SNFPA ROD, pg 41).
- Improved continuity and distribution of old forest ecosystems and habitats as well as associated wildlife species (2004 SNFPA ROD, pg 41).

Measurement Indicators: Changes in old forest vegetation (acres and % remaining), changes in old forest vegetation with regard to associated wildlife species (acres and % remaining on several scales (wildlife analysis area – nesting/foraging, territory – suitable habitat, home range core area (HRCA) – suitable habitat, nest core – suitable habitat, protected activity center (PAC)).

Purpose and Need 4: Improve aspen and cottonwood growing conditions

Objective: Improve aspen and cottonwood growing conditions by releasing aspen and cottonwood stands from conifer competition, as well as stabilizing an eroding stream channel within one of these stands.

Need for Action

Aspen and cottonwood stands located in the Ingalls project area are low in health and vigor as well as productivity, which may be due to one or more of the following factors: past fire suppression, natural succession that favors conifers in the competition for sunlight and moisture, past grazing practices, or human-caused changes to the local hydrologic regime (e.g. roads). Field evaluation indicates that, regardless of the relative contribution of these various factors, competition by conifers is a major factor in the decline of these stands. Reducing the shading effects from adjacent conifers would allow for aspen and cottonwood stand expansion and sprouting leading to an increase in health, vigor and productivity of the stands.

Aspen and cottonwood stands need to be released from conifer competition to create healthier growing conditions and maintain the individual aspen or cottonwood clones.

Excessive streambed and bank erosion is detrimental to riparian aspen and cottonwood stands due to the loss of water table elevation and the subsequent loss of vegetative community types that are dependent upon a stable riparian system. Stabilizing and re-vegetating an eroding stream channel within one of the aspen and cottonwood stands would improve the health, vigor, and productivity of the stand by providing improved growing conditions for young cottonwoods.

Desired Conditions

The desired conditions for aspen and cottonwood stands would be:

- Expansion of aspen and cottonwood stand.
- Increased aspen and cottonwood sprouting.
- Multi-layered, multi-aged aspen and cottonwood canopies.
- Increased health and vigor of the stands.
- Maintained individual aspen and cottonwood clones.
- Improved stream channel stability in the stand.

Measurement Indicators: Ratio of conifers to aspen and cottonwoods in stands and increase in the number of aspen and cottonwood sprouts per acre.

Purpose and Need 5: Contribute to the economic health and stability of local rural communities

Objective: Provide forest products that contribute both directly and indirectly to the local economy, local forest products industry and infrastructure, and subsequently, local community stability.

Need for Action

There are several rural communities within reasonable distance of the project area. These communities are heavily dependent on the forest products industry for jobs and revenues. These communities are isolated from urban job markets, resulting in their reliance on natural resource-based industries. Since the mid-1980’s, the number of sawmills within the geographic area have dwindled from six to two, with one currently located in the Plumas County seat, Quincy, CA and one in Chester, CA. In addition to these sawmills, there are co-generation plants in Quincy, in Loyalton, CA (which is currently closed) and in Wendel, CA (which only takes biomass for the generation of electricity). Previously the co-generation plant in Loyalton was also a log mill that closed in the late 1990’s. The loss of these sawmills has reduced the number of jobs that provide living wages, as well as negatively affected the tax base of Plumas and Sierra Counties. This downturn has also negatively affected local roads and school districts, which rely on timber receipts generated from Federal timber sales. The 1998 HFQLG FRA was passed, in part, to address these economic concerns.

Desired Conditions

The desired conditions for contributing to the economic health and stability of local rural communities would be:

- A continuous, regulated flow of forest products from National Forest System activities, providing for commercial product removal, that contribute both directly and indirectly to local economies.

Measurement Indicators: total number of direct and indirect jobs, sawlog volume (mmbf), total employee related income and cost of implementation.

Purpose and Need 6: Provide the road access needed to meet project objectives while reducing transportation system effects

Objective: Provide an effective and operable road system to meet project objectives while reducing effects on natural resources.

Need for Action

Roads play a vital role in providing access for resource management, as well as public access for recreation use. However, unneeded and poorly located roads can impair and impact watersheds.

In the Ingalls Project area, some roads are narrow and unimproved, making access difficult for commercial logging trucks and chip vans, while other roads within the Project area contribute to erosion and resultant stream channel sedimentation. Roads located near riparian habitat conservation areas (RHCAs) can produce increased peak flows and decrease channel stability. Both sediment loading and the loss of hydrologic function within RHCAs are causing resource damage in the form of degraded water quality, aquatic habitat, and overall watershed health. For example, roads that are identified for decommissioning and/or obliteration are causing resource damage by adding sediment to RHCAs, are dead-end spurs, and/or are interfering with water flow in stream channels. One of the purposes of the HFQLG Act is a program of riparian management and restoration. This includes use of an interdisciplinary process to evaluate each of the HFQLG project areas for potential resource damage caused by roads. The interdisciplinary process for identifying road system needs and roads with resource damage includes a roads analysis consistent with legal requirements (36 CFR 212 Subpart A – Administration of the Forest Transportation System, 16 U.S.C. 551, 23, U.S.C. 205).

Desired Conditions

The desired conditions for providing the road access needed to meet project objectives while reducing transportation system effects would be:

- Access provided for resource management by Forest Service personnel.
- Public access for recreation purposes.
- Decreased number of roads that are causing resource damage.

Measurement Indicators: Miles of improved road, restored hydrologic function (acres).

Laws, Regulations, and Policy that Influence the Scope of this EA

Herger-Feinstein Quincy Library Group Forest Recovery Act (1998)

On October 21, 1998, the President of the United States signed the *Department of the Interior and Related Agencies Appropriations Act*, including section 401—the *Herger-Feinstein Quincy Library Group Forest Recovery Act* (HFQLG Act). The HFQLG Act states that the Secretary of Agriculture, acting through the Forest Service, and after completion of an Environmental Impact Statement (EIS), shall conduct a pilot project for five years on federal lands in the Lassen and Plumas National Forests and the Sierraville Ranger District of the Tahoe National Forest.

The HFQLG Pilot Project is designed to test and demonstrate the effectiveness of certain fuels and vegetation management activities in meeting ecologic, economic, and fuel-reduction objectives. Full implementation of the HFQLG Pilot Project would balance good silvicultural practices, economic efficiency with ecosystems, watersheds, and other forest resources protections.

Herger-Feinstein Quincy Library Group Forest Recovery Act EIS, Supplemental EIS, Records of Decision (1999 and 2003) and Appropriations Acts, (extending the HFQLG FRA Pilot Project), and the Healthy Forest Restoration Act (2003)

The HFQLG Act EIS was completed on August 17, 1999, and the Record of Decision was signed on August 20, 1999 (USDA Forest Service 1999). The Record of Decision amended the land and resource management plans for three National Forests (Plumas, Lassen, and Tahoe) and gave direction to implement the resource management activities required by the HFQLG Act. The Record of Decision on the HFQLG final supplemental EIS addressing DFPZ maintenance was adopted on July 31, 2003 (USDA Forest Service 2003). In February 2003, the *Department of the Interior and Related Agencies Appropriations Act* was signed and extended the HFQLG Pilot Project legislation for another five years. In December 2007, the *2008 Consolidated Appropriations Act* extended the HFQLG Pilot project to September 30, 2012. It also applied some portions of the *Healthy Forest Restoration Act (HFRA)* (Sections 104-106) to HFQLG projects. These sections relate to environmental analysis, public notice, comment and objection processes, and judicial review. In March 2009, the *Omnibus Appropriations Act* amended this, clarifying that Section 106 of the *Healthy Forest Restoration Act* (related to expedited judicial review) *shall* apply to all HFQLG projects, while Sections 104 and 105 (related to environmental analysis and objection processes) *may* be applied to HFQLG projects.

Sierra Nevada Forest Plan Amendment (SNFPA) ROD and Final Supplemental EIS (2004)

In January 2004, the Regional Forester signed the SNFPA final supplemental EIS Record of Decision, which replaced the 2001 Record of Decision on the SNFPA final EIS and changed management direction to allow full implementation of the HFQLG Pilot Project, consistent with the goals identified in the HFQLG Act. The 2001 SNFPA final EIS and Record of Decision are incorporated by reference in the 2004 Record of Decision on the SNFPA final supplemental EIS.

The 2004 Record of Decision on the SNFPA final supplemental EIS directed the Plumas National Forest to implement the HFQLG Pilot Project, which includes creation of DFPZs for the proposed project. These activities are needed in order to limit the potential size of high-intensity wildfires and loss of resources. DFPZs are strategically located and designed strips of land where surface fuels (excess down woody material), ladder fuels, and canopy fuels are reduced so that large, destructive canopy fires would lose intensity and transition to surface fires. DFPZs are wide enough to capture short-range spot fires in the treated area and are designed to provide fire suppression personnel a safe location from which to take fire-suppression actions. DFPZs are usually strategically located along roads, ridgetops, meadows, or rocky areas to enhance their effectiveness and accessibility.

Forest Plan Direction (1988)

The 1988 *Plumas National Forest Land and Resource Management Plan* (commonly referred to as the "LRMP"), as amended by the 1999 HFQLG final EIS Record of Decision, the 2003 HFQLG FRA Supplemental EIS and ROD and as amended by the 2004 SNFPA final supplemental EIS Record of Decision, guides the Proposed Action and alternatives. The 2004 SNFPA Record of Decision (page 68) displays the standards and guidelines applicable to the HFQLG Pilot Project Area. Land allocations that apply to this proposed project include Off-base and Deferred Lands, late-successional old-growth forest, California spotted owl Protected Activity Centers, and Spotted Owl Habitat Areas and the NFS lands outside these allocations that are available for vegetation and fuels management activities.

Project Schedule

The responsible official expects to make a decision on this project as early as the summer of 2011. Implementation could begin as early as fall of 2012.

Decision to be Made

The Responsible Official for the Ingalls Project would be the Forest Supervisor for the Plumas National Forest. The Responsible Official would decide whether to implement the Ingalls Project as stated in the Proposed Action, as modified by an alternative, or not to implement the project at this time.

Public Involvement and Scoping Issues

Public Collaboration

The District gave a presentation to the Plumas Fire Safe Council as part of the HFRA collaboration process on June 12, 2008. Written comments were received from the Plumas County Fire Safe Council. Comments were considered in the design of the Ingalls Project Proposed Action.

Notice of the pending action first appeared in the Plumas National Forest quarterly Schedule of Proposed Actions (SOPA) as the "Ingalls Project" in 2009, and has been on each subsequent SOPA. As required by HFRA, the Beckwourth Ranger District held collaborative public meetings prior to the development of the Proposed Action. An open house was held on November 12, 2009 at the Beckwourth Ranger District. No comments were received. A second public meeting on December 12, 2009 at the Eastern Plumas Health Care Education Center was canceled due to bad weather.

There were two additional collaborative meetings held with members of Sierra Forest Legacy and Quincy Library Group. Based on discussion at these meetings, a recent Technical Report "An Ecosystem Management Strategy for Sierran Mixed-Conifer Forests (PSW-GTR-220 2009)" was used for design features, where they were consistent with direction in the 1988 LRMP as amended.

The District started the HFRA 218 objection process and NEPA scoping process with publication in the Feather River Bulletin (and Portola Reporter) on May 12, 2010. The packet was mailed to Native American entities (including federally recognized tribal governments, tribal groups currently applying for federal recognition and Native American organizations/non-profit groups), that are interested in projects that are located on this portion of the PNF. Eighteen Proposed Action description packets (Proposed Action, figures and maps) were sent to various individuals, organizations and government agencies. The scoping period ended on June 11, 2010 (Table 1).

Table 1. People and organizations that provided comments on the proposed action of the Ingalls Project and the date the comments were received.

Entity	Representative	Date Received
Sierra Forest Legacy	David Edelson and Craig Thomas	March 25, 2010
Sierra Pacific Industries	Brian Wayland	March, 16, 2010

QLG Counties' Forester	Frank Stewart	March 13, 2010
Plumas Fire Safe Council	Brian West	March 11, 2010

The purpose of the objection process/scoping process was to inform the public about the Proposed Action, Purpose and Need in order to seek different points of view on the pending actions and issues to be addressed during the project analysis period.

Representatives from the Quincy Library Group, Sierra Forest Legacy, Sierra Pacific Industries and Natural Resource Conservation Service attended an additional collaborative public field trip to the Ingalls project area on September 22, 2010.

Issues

The interdisciplinary team considered the scoping comments to identify potential issues and any potential effects of the Proposed Action. No issues that would drive new alternatives were identified by the team for the project. However, commenters did request consideration of additional alternatives; these are discussed in Chapter 2 of this EA.

Chapter 2. Alternatives, Including the Proposed Action

Contents of Chapter 2

This chapter provides the reader with a detailed description of the Proposed Action, action alternatives, the No Action Alternative and the Alternatives Considered but Eliminated from Detailed Study. Each section illustrates the differences between the alternatives and the issues to which the alternatives respond. In addition to the action alternatives, a No Action Alternative is analyzed to determine the effects of taking no action.

Chapter 2 is organized as follows:

- Alternatives Considered in Detail
- Project Specific Design Features and Mitigations
- Comparison of Alternatives
- Alternatives Considered but Eliminated from Detailed Study

Chapter 2 follows the CEQ regulations 1502.14 for implementing NEPA, which require the Forest Service to rigorously explore and objectively evaluate all reasonable alternatives and briefly discuss the reasons for eliminating any alternatives. This process was done with resource specialists in an interdisciplinary team (IDT) setting. The IDT discussed the potential benefits and costs of the action alternatives and Alternatives Considered but Eliminated from Detailed Study.

Alternative 1 - Proposed Action

Minor Corrections/Changes to the Proposed Action

On May 12, 2010, the document titled “Ingalls Project Proposed Action” was mailed to the public. Since that time a few changes have been noted in the Proposed Action due to internal clarifications and additional collaborative meetings with the public. These changes are reflected in the Proposed Action (Alternative 1) as follows:

The Proposed Action stated that Group Selection activities would only occur within Area Thin units for a total of approximately 42 acres. This has changed. Group selection activities could occur within both DFPZ and Area Thin units, but not to exceed a total of 42 acres.

The Proposed Action stated that a total of 4,580 acres would be treated across the project area. Within DFPZ units there were 1,641 acres of mechanical thinning, 306 acres of mechanical fuels treatment, 915 acres of underburn, and 1,024 acres of no treatment. Within Area Thin units, a total of 600 acres would be treated with mechanical thin. Within Aspen and cottonwood units, a total of 94 acres would be treated. This has changed as more site specific field evaluations have occurred. Total treatment proposed has decreased to 4,095 acres. Additionally, mechanical fuels treatment has been split into mastication, grapple pile with hand thin, and hand thin options. Table 2 shows the new summary of actions by treatment type.

The Proposed Action stated that a total of 7 miles of system and non-system roads would be decommissioned/or obliterated. This has changed based upon further collaboration with interested parties. In order to enhance recreation opportunities on the Beckwourth Ranger District, the proposed non-system road 111C, with mitigations, would become a system road (0.59 miles). In addition, system road 25N90, previously proposed for decommissioning, would remain open with mitigations. A non-system portion of this road would still be obliterated due to resource concerns.

Alternative 1- Proposed Action

The Proposed Action was designed to meet the Purpose and Need discussed above: 1) strategically reduce fuel loads, 2) increase forest health and fire resiliency, 3) provide for old forest ecosystems and associated wildlife species, 4) improve aspen and cottonwood growing conditions, 5) contribute to the economic health and stability of local rural communities and 6) provide the road access needed to meet project objectives while reducing transportation system effects on resources in the project area. The Proposed Action treatment for DFPZ units includes mechanical thinning, group selection, grapple piling, mastication, hand thinning, underburning and aspen and cottonwood release (Table 2). In addition, some units within the DFPZ would receive no treatment because they already meet desired conditions for the DFPZ. Treatment for Area Thin units (areas outside of the DFPZ) includes mechanical thinning, group selection, underburning and aspen and cottonwood release (Table 2).

In addition to project specific design features and mitigations described with each alternative, the District would implement standard operating procedures (SOPs). SOPs represent standard mitigations intended to minimize potential for adverse resource effects. Area Thin units fall under the Area Thin Standards and Guidelines, as opposed to DFPZ units, which fall under the DFPZ Standards and Guidelines. Aspen treatments are in Riparian Habitat Conservation Areas (RHCAs) which must meet the Riparian Management Objectives (RMO).

Table 2. Summary of actions proposed in the Ingalls Project area.

Actions	Acres (approximate)
DFPZ	
Mechanical thinning	1,231
Mastication	166
Grapple pile with hand thin	110
Hand thin with underburn	780
Underburn	343
No treatment	771
Total DFPZ	3,401
Area thin	
Mechanical thinning	599
Total area thin	599
Aspen/cottonwood thin	
Mechanical thinning	95
Total aspen/cottonwood thin	95
Grand Total	4,095

Reduce fuel loads, improve forest health and fire resiliency, and provide for old forest ecosystems and associated wildlife species

Mechanical Thinning in DFPZ and Area Thin units

Mechanical thinning treatments would include the use of ground-based logging systems on 1,231 acres within DFPZ units and 599 acres within Area Thin units (Table 2). Ground-based logging equipment can treat up to 35% slope. In general, ground-based logging equipment would remove trees under approximately 20 inches dbh using whole tree yarding. Trees that are greater than 20 to 29.9 inches dbh would be hand felled, bucked to log lengths, limbed, topped, and skidded to the landing. No trees 30 inches dbh or greater would be removed except in unavoidable cases for operability and safety.

Variable Density Thinning

Variable density thinning is a compilation of various thinning treatment elements: a) structural thinning b) radial release of fire-resilient legacy trees and c) wildlife structural diversity patches. Each of these elements is described below in more detail. This combination of activities would promote heterogeneity (a mixture of tree sizes) within a stand and across the landscape, as well as increase structural diversity that provides a variety of wildlife habitat elements, while creating a fire-resilient stand. A percentage of smaller trees would be left for diversity, structure, and to provide for the next generation of forest. The variable density thinning action (structural thinning and radial release) would be applied to all DFPZ and Area Thin units. Canopy cover and basal area would be highly variable across treatment units, but would follow the Standards and Guidelines in the 1988 LRMP, as amended by Table 2, 2004 SNFPA ROD. Within the Area Thin units, wildlife structural diversity patches would be established in control areas where no treatment would occur. Wildlife diversity patches would be located in areas that provide habitat elements for old forest ecosystem wildlife species.

Table 3. Design criteria for mechanical thinning (variable density thinning) actions under the Proposed Action.

Criterion	Design
Structural Thinning Prescription	• Healthy fire-resilient tree species (ponderosa pine, Jeffery pine, sugar pine, and Douglas-fir) within all size classes would be preferentially retained. • Thinning would occur through all size classes up to 29.9" dbh to improve stand level heterogeneity. • Basal area would vary across the stand due to the creation of "clumps" and "gaps." Residual basal area densities would vary by stand designation (DFPZ, Area Thin) and ecosystem type (eastside pine, mixed conifer, true fir). • Removal of trees ≥ 30" dbh would not occur, except in unavoidable cases regarding operability and safety due to Occupational Safety and Health Administration (OSHA) regulations. In such instances Forest Service Representative must approve their removal.

Radial Thinning Prescription	• Selection of fire-resilient legacy trees for retention would include the following attributes:
	  • Species preference in order of importance: Jeffery pine, ponderosa pine, sugar pine, Douglas-fir and incense cedar
	  • Trees over 24" dbh would be selected for retention when available
	• Radial thinning distance would vary depending on physical and site attributes such as slope, aspect and soil moisture holding capacity.
	• Trees retained can be either individual trees and/or clumps of trees.

Wildlife Structural Diversity Patches (Area Thin units only)	• Areas would be retained that have the following characteristics:
	  • multi-layer canopies (greater than 2 layers)
	  • all-aged stand
	  • higher percent canopy cover compared to adjacent areas
	  • snags and large woody debris, where possible
	  • vertical and horizontal structural continuity and diversity
	• Control Areas (areas where no treatment occurs) such as RHCAs, equipment exclusion zones, cultural resource sites and botanical areas, would be evaluated for retention characteristics.
	• Patches would not be located within DFPZ units.

Follow-up Fuel Treatments	• Hand thinning, grapple piling, mastication and/or underburning may follow initial treatment, if needed to meet surface, ladder and canopy fuel-reduction objectives.

Grapple Piling, Mastication, Hand Thinning and Underburning in DFPZ units

Grapple piling, mastication and hand thinning would occur on 1,056 acres. Underburning is the only treatment proposed on 343 acres for DFPZ units only (Table 1, Appendix A-2).

Grapple piling is an effective treatment for high surface fuel loads on steep ground (up to 45% slope using tracked equipment). Grapple piling equipment generally involves a tracked excavator that can physically move dead and downed fuels and live brush. In addition to piling surface fuels, live and dead conifer trees <11.9" dbh would be felled by a sawyer and piled with the excavator. In addition, dead and downed material and live brush may also be piled. The excavator would pile material in the treatment unit, which would receive subsequent burning.

Mastication equipment does not remove the material from the site, but rearranges the fuel configuration from ladder fuels to surface fuels. Mastication is a possible alternative, depending on terrain (up to 45% slope) and the existing fuels situations. Mastication involves the chewing or grinding of vegetation, leaving wood chips, which would not exceed 6” in depth. By leaving chips on site, there are no piles to burn and organic material eventually returns to the soil.

Hand thinning treatments would be required in order to limit tree mortality during underburn prescriptions. Trees <8” dbh that are considered ladder fuels would be felled, lopped and scattered. Units would then be underburned.

Table 4 displays the design elements for mechanical fuels treatments and underburning activities for DFPZ treatments for the Proposed Action.

Table 4. Design elements for mechanical fuel treatments and underburning for DFPZs under the Proposed Action.

Criterion	Design
Grapple Piling with Hand Thinning	• Cut conifer trees <11.9”dbh and pile with mechanical equipment. • Pile dead and downed material and live brush. • Piles would be burned • Slopes up to 45% would be treated.
Mastication	• Brush and trees <11.9” dbh would be treated. • Fuel depths would not exceed 6”. • Slopes up to 45% would be treated.
Hand Thinning	• Conifer trees <8” dbh would be felled, lopped and scattered. • Units would be underburned.
Follow-up Fuel Treatments	• Grapple piles would be burned. • Except where prohibited, fire would be allowed to creep between piles during pile burning to provide for a concurrent understory burn • All units would be evaluated for underburning post-treatment.
Underburn Prescription Only	• Stands that already meet DFPZ desired conditions would be evaluated for underburn only.

Group Selection in DFPZ and Area Thin units

Group selection would occur on a total of approximately 42 acres within DFPZ and/or Area Thin units. Each group selection unit would be 1/2 to 2 acres in size. Group selection is an uneven-aged method of regenerating an area. Groups improve diversity, future fire-resiliency, and forest health by reducing the overabundance of white fir in some areas and allowing the re-growth of pine species. Groups would be located in dense white fir stands that are declining in health due to density related tree mortality. Seed trees would be left when they are available and conditions permit for natural regeneration and to maintain some structural diversity within each group. Ground-based logging equipment can treat up to 35% slope. In general, ground-based logging equipment would remove trees under approximately 20 inches dbh using whole tree yarding. Trees that are between 20 to 29.9 inches dbh would be hand felled, bucked to log lengths, limbed, topped, and skidded to the landing. Table 5 displays the design elements for group selection for DFPZ and Area Thin units under the Proposed Action.

Table 5. Design elements for group selection for the Proposed Action.

Criterion	Design
Group Selection Prescription	• Size 0.5 to 2 acre openings • Remove all trees up to 29.9" dbh, except for potential seed sources of fire resilient tree species to help enhance natural regeneration (sugar pine, ponderosa pine, Jeffery pine). • Removal of trees ≥ 30" dbh would not occur, except in unavoidable cases regarding operability and safety due to Occupational Safety and Health Administration (OSHA) regulations. In such instances Forest Service Representative must approve their removal.
Group Selection Locations	• Soils capable of supporting conifer regeneration. • Groups would be restocked if they have not reforested within 5 years naturally. • Groups would be located within white fir stands or target pockets of pest and/or disease. • Groups would not be located within riparian habitat conservation areas (RHCA). RHCAs are described in the SOPs, consistent with the HFQLG 1999 FEIS.

Improving Aspen and Cottonwood Growing Conditions

The Proposed Action would treat approximately 95 acres within DFPZ and Area Thin units of aspen and cottonwood stands to improve growing conditions. Within the Ingalls Project, there are two types of aspen/cottonwood stands: meadow fringe aspen communities and riparian aspen communities (Sheppard et al. 2006). Conifer removal would occur within the existing stand (i.e. those trees actively suppressing community productivity and function) and include trees 1 to 1 ½ tree heights past the aspen and/or cottonwood root zone, but treatment would vary depending on the type of aspen/cottonwood stand. Table 6 displays the design elements for improving aspen and cottonwood growing conditions under the Proposed Action.

Currently there are a series of head cuts, gullies and areas of streambank instability within Aspen Stand 003. The proposed treatments include armoring the head cuts with rock and filling in the new channel in the streambed with on-site fill material and sloping upward towards the head cut from downstream in order to dissipate energy coming over the head cut. Vertical banks may be re-contoured to expedite the natural process of vertical banks eroding until they reach the natural angle of repose. In addition, willow and cottonwood plugs could be collected from the surrounding area in channel and adjacent to the channel and transplanted into denuded re-sloped streambanks. Where needed, banks would be seeded and mulched with weed-free straw or covered with erosion cloth blankets.

Table 6. Design elements for aspen and cottonwood treatments under the Proposed Action.

Criterion	Design
General Aspen/Cottonwood Prescription	• Conifers up to 20" dbh may be removed using whole tree yarding. Conifers 20-29.9" dbh may be hand felled, bucked and endlined. • Follow-up hand thinning could occur. • Canopy cover restrictions would not apply. • Conifers (<11.9" dbh) located with RHCA/SMZ equipment exclusion zones would be hand thinned, piled and burned. • Cottonwood plugs could be planted following thinning work.
Meadow Fringe Aspen/Cottonwood Type (units 37, 38 and 39)	• Conifers could be removed within the stand and within the extended treatment zone extending up to 1 to 1 ½ aspen tree heights past the root zone. The root zone would be determined by locating the furthest location of suckers.
Riparian Aspen/Cottonwood Type (Units 3, 5, 8, 9, 12,19 and 41)	• Conifers could be removed within the stand and within the extended treatment zone extending up to 1 to 1 ½ aspen tree heights from existing aspen trees within the stand.
RHCA/SMZ Constraints	• A no-equipment exclusion zone (15 feet wide) would be established along each side of the stream channel to ensure no disturbance to bank stability. Equipment may be positioned outside of the buffer and harvest/gather material via an extendable harvest arm attachment. • Conifers providing bank stability would not be removed regardless of species. • Crossing stream channels with mechanical equipment would be allowed under special circumstances and with coordination between the hydrologist and Forest Service Representative. If a stream channel is crossed, the contractor would be required to return the channel banks back to their natural contour. • Landings would be located outside of the stand perimeter and RHCAs whenever possible.
Follow-up Fuel Treatments	• Aspen and cottonwood units would not be underburned or subsoiled unless agreed to by a silviculturist in conjunction with a hydrologist and a fuels specialist.

Provide the road access needed to meet project objectives while reducing transportation system effects in the project area

The road-related work proposed with this project has been coordinated with the on-going Plumas National Forest Public Motorized Travel Management Plan. In summary a total of approximately 5-miles of system and non-system roads would be decommissioned, closed and/or obliterated, 14 miles of reconstruction would facilitate fuels and silviculture activities and improve drainage features, and approximately 8 miles of temporary road would be constructed or reconstructed and subsequently restored. For specific information on specific roads that would receive decommissioning, refer to Appendix D.

Forest access needs and new temporary road location must follow the Riparian Management Objectives (RMO), as directed by the 1999 HFQLG EIS/ROD Appendix B. The non-system road 111C was originally proposed for obliteration due to resource concerns. Upon further collaboration with interested parties this non-system road would be added to the system once the resource concerns had been mitigated. Table 7 displays the design elements for road access under the Proposed Action.

Table 7. Design elements for road access under the Proposed Action.

Criterion	Design
Decommission/Obliteration	• Decommissioning/Obliteration may involve recontouring, subsoiling or abandonment. Abandonment is appropriate where the road has become completely overgrown with vegetation. Decommissioning/Obliteration may also involve removing drainage structures, restoring vegetative cover, blocking access or some combination of these treatments.
Maintenance	• Maintenance would consist of brushing, blading the road surface, improving drainage.
Reconstruction	• Reconstruction may involve the removal of all trees from within the road prism as well as brushing, blading the road surface, improving drainage and replacing/upgrading culverts where needed.
New Temporary Roads	• Temporary roads would be constructed for project work and subsequently restored when the fuels and vegetation management work is complete.

Alternative 2 – No Action Alternative

This alternative serves as a baseline for comparison among the alternatives, and is required by the implementing regulations of the National Environmental Policy Act (NEPA). This alternative takes no action at this time to implement provisions of the 1998 HFQLG Act on this part of the Plumas National Forest. Current, on-going activities such as routine road maintenance, fire suppression and recreation would still occur in this area. However, treatments designed to help firefighters reduce the spread of crown fires through strategic placement of DFPZs, reduce hazardous fuels, improve forest health, promote old forest ecosystems and associated species, support the local economy or reduce the impacts of roads would not occur. Since forest ecosystems are not static, they would still continue to change as a result of naturally occurring dynamic forces such as forest succession and wildfires. The current existing condition of high fuel loading, diseased and overstocked stands and road impacts would not be addressed under the No Action Alternative.

Alternative 3 – Non-Commercial Funding Alternative

Developing Alternative 3

A recent court ruling requires all projects with a singular purpose and need for fuels reduction, or with multiple purposes and needs that include fuel reduction, must have a non-commercial funding alterantive. A non-commercial funding alterantive is an alterantive where the sole purpose is to achieve the fuels reduction element of the purpose and need and where all the proposed treatments are soley directed at reducing hazardous fuels. In a non-commercial funding alterantive, there can be no additional timber harvesting beyond that need to meet the fuels reduction purpose and need (*Sierra Forest Legacy v. Mark Rey,* Case 2:05-cv-00205-MCE-GGH, Morrison C. England, Jr, United States District Court Judge, United States District Court, Eastern District of California, November 4, 2009).

Alternative 3 includes DFPZ treatments, which would be implemented to accomplish the purpose and need for modifying fire behavior only (Appendix E-3). No other treatments proposed under Alterantive 1 would be proposed under this alterantive.

Design features for Alternative 3

Strict Thin from Below in DFPZ

This alternative would solely meet the fuels reduction purpose and need. There would be no additional timber harvesting beyond that needed to meet the fuel reduction purpose and need. This alternative would limit timber harvest by restricting the removal of trees that meet any other objective such as fire resiliency, stand health, aspen or cottonwood restoration, or economic returns to the local community beyond that needed to meet the fuel reduction purpose and need. In order to meet the purpose and need for fuels reduction, this alternative would reduce surface, ladder and canopy density. Surface fuels would be addressed through underburning and whole tree yarding. Ladder fuels would be addressed by removing understory and intermediate trees to achieve the reduction in stand density necessary to achieve DFPZ standards. Canopy density would be addressed by removing trees in the upper canopy when needed for a reduction in overall canopy bulk density up to the upper diameter limits. Units would be treated with a thin from below silvicultural prescription using upper diameter limits that range from 8 to 16 inches (based on modeling, see Fire and Fuels section in Chapter 3). This alternative would utilize a strict thin from below, limiting the effectiveness in creating a desired species composition (Table 8).

Table 8. Design elements for actions under Alternative 3.

Criterion	Design
Mechanical Thin using Thin from Below	• Strict thin from below with no preference for species. • Variation in the remaining stand would be incidental. • Units would be treated with a thin from below silvicultural prescription using upper diameter limits that range from 8 to 16 inches.

Reduce fuel loads, improve forest health and fire resiliency, and provide for old forest ecosystems and associated wildlife species

Unlike the Proposed Action, this alternative would only treat fuels located in the DFPZ as a strict thin from below prescription, no treatment would occur in the area thin units. This alternative would not provide for old forest ecosystems and associated wildlife species.

Improving Growing Conditions for Aspen and Cottonwood Stands

Unlike the Proposed Action, this alternative proposes no aspen or cottonwood treatment. The reason is that the sole focus of the alternative is to reduce fuels.

Provide the access needed to meet project objectives while reducing transportation system effects in the project area

Alternative 3 would not decommission any roads or implement watershed restoration actions. Table 9 displays proposed activities that would occur with Alternative 3. For specific details regarding which roads would receive road treatments, see Appendix D, Table D.3. Table 9 displays the design features for road treatments under this alternative.

Table 9. Design elements for road treatments under Alternative 3.

Criterion	Design
Maintenance	• Maintenance would consist of brushing, blading the road surface, improving drainage.
Reconstruction	• Reconstruction may involve the removal of all trees from within the road prism as well as brushing, blading the road surface, improving drainage and replacing/upgrading culverts where needed.
New Temporary Roads	• Temporary roads would be constructed for project work and subsequently restored when the fuels and vegetation management work is complete.

Project Specific Design Features and Mitigations

In addition to the SOPs (Appendix B), the following design features have been developed for the Ingalls Project. The mitigation measures listed below are common to all action alternatives.

Air Quality

Specific air quality mitigations for pile burning and broadcast burning would include number of acres burned daily, preferred wind directions for smoke travel and weather conditions, which would allow for smoke dispersal. This would allow for piles to dry before ignition and ceasing ignitions if smoke dispersion conditions degrade. Monitoring of smoke transport is required by National Smoke Air Quality Management District (NSAQMD). These mitigations would be agreed upon with the NSAQMD and addressed in the Smoke Management portion of those burn plans developed for the Ingalls Project.

Botany

To protect sensitive and special interest plant species, as well as unique and unusual botanical habitats the following control areas would be established. Control areas would be flagged prior to project implemention; they would not be disturbed by project activities.

Noxious Weeds

In order to prevent and/or reduce the spread of noxious weeds, SOPs would be applied such as requiring that all off-road equipment and vehicles be weed free, use of weed free seed sources and avoiding areas of known weed occurrences including outside the units and project area. Control areas would be flagged prior to project implemention. Control areas would not be disturbed by project activities.

Cultural Resources

Detailed cultural resource information about the location, character, or ownership of a historic resource is withheld from disclosure here because sharing this information may cause an invasion of privacy, may risk harm to the historic resources or may impede the use of a traditional religious site by practitioners [Section 304 of National Historic Preservation Act, 16 U.S.C. 470w-3(b)]. Therefore specific mitigations for cultural resources are not publicly documented.

Soil and Watershed

Treatment would be implemented so that effective post treatment ground cover would meet cover values. Where vegetation removal is proposed within RHCAs outside of apsen and cottonwood treatment units, post treatment canopy cover in RHCAs would be preserved at greater than 40 percent.

Wildlife

- **Wildlife Trees:** These trees would be 24" dbh or greater and provide structure beneficial for wildlife use. Suitable trees can be identified by certain desirable characteristics such as teakettle branches, large diameter broken tops, and large cavities located within the tree's bole.
- **Hardwoods:** Hardwoods will be favored for leave status and left standing. This includes species such as black oak, aspen and cottonwood. Retain oaks to enhance species composition, age diversity and structural heterogeneity. Gaps can focus on clumps of smaller younger oaks. This would potentially enhance the expansion of oak by encouraging growth in areas of lower conifer shading.
- **Large woody debris:** Large woody debris (LWD) shall be retained at 2004 SNFPA FSEIS ROD standard and guidelin levels, where available (10-15 tons/acre ≥12 inches diameter).
    - In areas considered deficient in large woody debris, cull logs would be left at the stump, where possible.
    - During mastication and grapple piling operations: Large woody debris should be left scattered across landscape.
    - In unit 4 the 5-6 existing down logs would be left in place during mechanical activities and lined prior to underburning.
- **Limited Operating Periods (LOPs):** The action alternatives would have the appropriate LOP applied as identified in .
- Table 10.

Table 10. Wildlife Limited Operating Periods for the Ingalls Project area. Operations would be limited during these periods over portions of the project area.

Unit or Road Number	Species	Limited Operating Period
Unit 1	California Spotted Owl	March 1st thru August 15th
Road 25N49, 25N99 NW of unit	California Spotted Owl	March 1st thru August 15th
Unit 2, 18, 19, 34	Northern Goshawk	February 15th thru September 15th

Units 10, 11, 12, 17 (possible)	Northern Goshawk	February 15th thru September 15th
Underburn Unit 45	Northern Goshawk	February 15th thru September 15th

- **Snags/Dead Trees:** Snags and dead trees shall be left, unless the tree poses a risk to personnel during operations, or is a risk to the public. Residual snags should be 15 inches and greater in diameter and 20 feet or more in height. Snag/dead trees classified as "hazard" will be marked for removal.
- **Structural Thinning:** Structural thin areas that are at the higher basal area range (clumps) may contain snags and leaning trees to favor wildlife retention. Lower basal area ranges (gaps) may contain "wolf" and "broom" trees.
- **Wildlife habitation and nest trees:** Trees that show signs of current habitation, including nesting activity shall be left standing and not removed.

Comparison of the Alternatives

This section provides a summary of the effects of implementing each alternative. Information in Table 11 is focused on activities and on effects where different levels of effects or outputs can be distinguished quantitatively, or qualitatively, between the alternatives.

Table 11. The Ingalls Project Purpose and Need comparing each Alternative.

	Alternative 1	Alternative 2	Alternative 3
Purpose and Need 1: Strategically Reduce Fuel Loads			
Measures of effective fuels reduction include:			
Average canopy base height (feet)	16.6	6.7	13
Average surface fuels (tons per acre)	5.5	20	5.28
Average flame length (feet)	0.8	9.9	0.7
Average percent mortality (%)	10	98	6.3
Measures of DFPZ connectivity and design placement:			
Topographic placement	Yes	No	Yes
Road adjacency placement	Yes	No	Yes
Tie to landscape features (i.e. roads, current vegetation types, rock outcrops)	Yes	No	Yes
Adjacent to planned or existing DFPZs	Yes	No	Yes
Purpose and Need 2: Improve Forest Health and Fire Resiliency			
Measures of forest health and fire resiliency include:			
Decreased risk of tree mortality (stand density index (SDI), stand basal area (BA),	Improved for most stand types	Continued increase overtime	Improved for some stand types, less benefit than Alternative 1.
Increased tree growth (tree ring width),	Yes	No	Yes
Tree species composition (FVS modeling and trees per acre (TPA) count),	Encourages	Discourages	Discourages
Tree stand structure (FVS modeling – quadratic mean diameter (QMD), BA, TPA, and canopy cover),	Multi-Storied	Multi-Storied	Single-Storied
Insect and disease risk (FVS modeling of risk).	Lowest	Highest	Reduced
Purpose and Need 3: Provide for Old Forest Ecosystems and Associated Wildlife Species			
Measures of old forest ecosystems include:			
Changes in old forest vegetation (acres and % remaining), immediate effects	-2 acres -0.12%	0	0
Changes in old forest vegetation with regard to California spotted owl (acres and % remaining	Nesting – 2 acres removed 99.8% of	100% of Nesting and Foraging	Nesting – 100% retained

(wildlife analysis area – nesting/foraging, territory – suitable habitat)	suitable habitat retained Foraging – 101 acres removed 99% of suitable habitat retained.	habitat retained. Higher long-term risk of loss.	Foraging – 267 acres removed. 98% of suitable habitat retained.
Changes in old forest vegetation with regard to associated wildlife species (acres and % remaining for home range core area (HRCA) – suitable habitat, nest core – suitable habitat,	33 acres reduced 99% of suitable habitat retained.	100% of HRCA habitat retained. Higher long-term risk of loss.	23 acres reduced. 99% of suitable habitat retained.
Changes in old forest vegetation with regard to Northern goshawk (acres and % remaining (wildlife analysis area – nesting/foraging, territory – suitable habitat)	Nesting – 103 acres removed 99% of suitable habitat retained Foraging – 131 acres removed 98% of suitable habitat retained.	100% of Nesting and Foraging habitat retained. Higher long-term risk of loss.	Nesting – 267 acres removed 98% of suitable habitat retained Foraging – increases by185 acres. 102% of suitable habitat retained.
Purpose and Need 4: Improve Aspen and Cottonwood Growing Conditions			
Measures of improved aspen and cottonwood growing conditions include::			
Ratio of conifers to aspen and cottonwoods	Improved	Reduced	Reduced
Increase in the number of aspen and cottonwood sprouts per acre	Improved/Increased	Decreased	Decreased
Purpose and Need 5: Contribute to the Economic Health and Stablility of Local Rural Communities			
Measures of economic health include:			
Total number of full-time jobs	165	0	117
Sawlog volume (mmbf)	7.4	0	1.1
Total employee related income	$6,591,000	$0	$4690,000
Total Project Value	($53,222)	$0	($890,490)
Purpose and Need 6: Provide the Road Access to Meet Project Objectives while Reducing Transportation Effects			
Measures of access include:			
Miles of improved road,	14	0	<13.3
Restored hydrologic function (acres)	0.6	0	0

Table 12. A summary of the number of acres of each silvicultural treatment occurring in each zone for the Ingalls Project area.

Action	Alternative 1	Alternative 2	Alternative 3
DFPZ			
Mechanical Thinning	1231	0	1231
Mastication	166	0	166
Grapple Pile with hand thin	110	0	110
Hand thin with underburn	780	0	780
Underburn	343	0	343
No Treatment	771	0	771
Total DFPZ	**3,401**	**0**	**3,401**
Area Thin			
Mechanical Thinning	599	0	0
Total Area Thin	**599**	**0**	**0**
Aspen/Cottonwood Thin			
Aspen/Cottonwood Thin	95	0	0
Total Aspen/Cottonwood Thin	**95**	**0**	**0**
Grand Total	**4,095**	**0**	**3,401**

Note: Acres may vary slightly during the final layout due to topography, stand condition, and rounding, etc.

Table 13. A summary of the number of miles of road treatment occurring in the Ingalls Project area.

Action	Alternative 1	Alternative 2	Alternative 3
Decommission/Obliteration of Roads	4.8	0	0
System Reconstruct	14	0	13.3
New Temporary Road Construction/Obliteration	8.4	0	3.9

Note: Mileages may vary slightly at the time of final road package development.

Other Affected Resources

Table 14: Other affected resources in the Ingalls Project area.

Other Resource Indicators	Alternative 1 (Proposed Action)	Alternative 2 (No Action)	Alternative 3
Cultural Resources			
Cultural Resources	No effect through use of SOPs	No effect	No effect through use of SOPs
Botany			
Sensitive Species – Lens-pod milk-vetch	May Affect Individuals, but is not likely to result in a trend toward Federal listing or loss of viability	No effect	Same as Alternative 1
Wildlife			
California Spotted Owl Nesting Habitat Loss (acres) (% remain)	2(99.8%)	0(100%)	0(100%)
California Spotted Owl Foraging Habitat Loss (acres) (% remain)	101(99%)	0(100%)	267(98%)
Northern Goshawk Nesting Habitat Loss (acres) (% remain)	103(99%)	0(100%)	267(98%)
Northern Goshawk Foraging Habitat Loss (acres) (%remain)	131(98%)	0(100%)	Increase by 185 acres (102%)
Great Grey Owl Nesting Habitat Loss (acres) (% remain)	50(92.3%)	0(100%)	45(93%)
Mesocarnivore Denning Habitat Loss (acres) (% remain)	300(91.6%)	0(100%)	132(96.3%)
Mesocarnivore Foraging Habitat Loss (acres) (% remain)	Increase by 197 acres (102%)	0(100%)	-135(99%)
Risk of Cumulative Watershed Effects – Equivalent Roaded Acre (ERA) values			
Number of watersheds with a Very High level of ERA (exceeds the Threshold of Concern (TOC) of 12% of watershed upland areas)	1	0	1

Number of watersheds with a Very High level of ERA (exceeds the Threshold of Concern (TOC) of 8% of watershed sensitive areas)	10	5	7
Number of upland areas of subwatersheds with a High level of ERA (9-12%)	3	0	3
Number of upland areas of subwatersheds with a Moderate level of ERA (6%-9%)	6	1	3
Number of upland areas of subwatersheds with a Low level of ERA (<6%)	6	12	11
Maximum sensitive area ERA value for any project watershed (as % of watershed area)	13.5	12.3	13.2
Maximum upland area ERA value for any project watershed (as % of watershed area)	14.5	13.9	13.4

Alternatives Eliminated from Detailed Study

Alternative 4 - 2001 SNFPA Alternative

One of the major components of the 2001 SNFPA was the 20" upper diameter limit over the majority of the forest, with higher limits in places like Urban Wildland Intermix Defense Zones and lower diameters in places such as Old Forest Emphasis areas (<12" dbh and do not reduce canopy in dominant and co-dominant by more than 10%). It also includes a number of other requirements such as higher canopy cover in certain areas, and no mechanical treatment in 25% of each stand to enhance heterogeneity. This alternative was eliminated from detailed study for the following reasons:

This alternative would not be able to incorporate the concepts of PSW GTR-220 (2009) or fulfill the majority of the project's purpose and need. Treatments would not be effective at meeting the purpose and need due to 2001 SNFPA restrictions. Within the Ingalls Project, approximately 64% (2,936 treatment acres) is old forest emphasis. The 2001 SNFPA guidelines would require areas that would receive mechanical treatment to have a 12" upper diameter limit, leave 25% of the area untreated, and not reduce the existing canopy cover by more than 10%. Of that 64%, 1,353 acres are not available for mechanical treatment because they are no treat areas (barren rocky areas) or are underburn only. That leaves 1,583 acres available for mechanical treatment with the 12" dbh limit and 25% (or 395 acres) receiving no treatment.

These restrictions would result in a thin from below prescription, which does not create the vertical and horizontal heterogeneity across the landscape that the Proposed Action would accomplish. The remaining acreage within Ingalls would follow the general forest standards and guidelines. An upper diameter limit of 20" dbh would be imposed with 25% of the stands receiving no treatment. Canopy cover would not be reduced by more than 20%.

Based on past experience, these treatments would not reduce the fuels adequately to meet the purpose and need for fuel reduction in the DFPZ. The Crystal Adams project (USFS BRD 2001) and Humbug Project (USFS BRD 2003), both on the Beckwourth Ranger District, were planned and implemented under the 2001 SNFPA. While the NEPA fuels modeling showed that many of the DFPZ fuels objectives could be met, field observations of these implemented projects have shown that the treatments yielded poor results in many areas (Crystal Adams HFQLG Project Evaluation Form, August 2006). Canopy cover was not reduced to the desired 40% and many ladder fuels remain, making the areas ineffective as DFPZs. In addition, the denser canopy cover and fuel ladders have resulted in higher mortality rates (20-50%) to the residual overstory during subsequent underburning and pile burning. The higher mortality rates required a third entry to remove trees that burned during the prescription. The requirement to leave 25% of each stand without mechanical treatment has resulted in some illogical gaps in the DFPZ network and patches of heavy fuel loading, not meeting the Purpose and Need for fuel reduction in the DFPZ.

Alternative 5 – HFQLG FRA fully implemented project with max acres of group selection

The commenter suggests that a fully implemented HFWLG FRA project with groups would be 504 acres for this project. This alternative was eliminated from detailed study because the project area has large areas that are not available for treatment or do not need treatment, and the remaining landscape has numerous openings. The available land base for Ingalls is significantly less than the total treatment acreage of 4,095 acres because of no treatment areas that meet desired conditions. The majority of the project area is hand thin with underburn or underburn only because it already meets DFPZ desired conditions, in addition to a large amount of no treat areas, mastication and grapple pile units. This leaves 1,832 acres available for group selection. If we maximize the number of groups for the 1,832 acres, it would amount to approximately 201 acres of groups (approximately 100 separate group selection units). However, not all of the 1,832 acres would be suitable for group selection. Within the Ingalls project area, the landscape is already highly fragmented due to past harvesting projects, natural land barriers such as rocky outcrops and poor growing site conditions. This would lead to further fragmentation thus not meeting our wildlife emphasis purpose and need or our forest health purpose and need.

Chapter 3: Affected Environment and Environmental Consequences

Introduction

This chapter summarizes the social, economic, physical, and biological environments that are affected by the Proposed Action, and the effects on the environment that would result from implementation of any of the alternatives. This chapter also presents the scientific and analytical basis for comparison of the alternatives presented in Chapter 2: Alternatives.

The “Affected Environment” section under each resource topic describes the existing, or baseline, condition against which environmental effects were evaluated, from which progress toward the desired condition can be measured. Environmental consequences form the scientific and analytical bases for comparison of alternatives through compliance with standards set forth in the Forest Plan. The environmental consequences discussion centers on direct, indirect, and cumulative effects. Effects can be neutral, beneficial, or adverse.

Direct and Indirect Effects

Direct effects are caused by the action and occur at the same place and time as the action. Indirect effects are caused by the action but occur later in time or further removed in distance, but are still reasonably foreseeable.

The environmental consequences presented in Chapter 3 address the impacts of actions proposed under each alternative. This effects analysis was done at the project level. Resource specialists reviewed each affected unit or road proposed in the alternatives.

As described in Chapter 2, for ease of documentation and understanding, the effects of the alternatives are described separately for distinct actions. The combination of these distinct actions is then added to the on-going and reasonably foreseeable actions in the cumulative effects analysis. The distinct actions analyzed for each alternative are mechanical thinning, mechanical fuels treatments, hand thinning and burning to strategically reduce fuel loads, increase forest health and fire resiliency, provide for old forest ecosystems and associated wildlife species, improve aspen and cottonwood stand growing conditions and provide access while reducing transportation system effects.

Cumulative Effects

According to the Council on Environmental Quality (CEQ) NEPA regulations, “cumulative impact” is the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such actions (40 CFR § 1508.7).

The cumulative effects analysis area varies according to the resource being analyzed. Past activities are considered part of the existing condition and are discussed in the “Affected

Environment" and "Environmental Consequences" sections under each resource. Appendix C provides a list of present, on-going and reasonably foreseeable future actions that could potentially contribute to cumulative effects.

In order to understand the contribution of past actions to the cumulative effects of the Proposed Action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

The cumulative effects analysis, for each specialist's cumulative effects section, with the exception of the Water and Soil Resource Effects Assessment, does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the Proposed Action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Furthermore, focusing on the impacts of past human actions risks ignores the important residual effects of past natural events. These important past events may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, "agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions".

Most of the specialists use the aforementioned cumulative effects analysis rationale, with the exception of the Water and Soil Resource Effects Assessment, where past actions over a 30-year period are used as an input to the Equivalent Roaded Acre analysis model. A list of past treatment types, year and acres are provided in a separate table.

Specialist Reports

Each section in this chapter provides a summary of project specific reports, assessments, and/or input prepared by Forest Service specialists, which are incorporated by reference into this EA. The following reports or memoranda are incorporated by reference: Ingalls Project Fire and Fuels

Report, Ingalls Project Air Quality Report, Ingalls Project Vegetation Management Report, Ingalls Project Economics Report, Ingalls Project Biological Assessment/Biological Evaluation (BA/BE) Terrestrial and Aquatic Wildlife, Ingalls Project Management Indicator Species (MIS) Report, Ingalls Project Migratory Bird Species Report, Ingalls Project Water and Soil Resource Effects Assessment, Ingalls Project Biological Evaluation for Threatened, Endangered, or Sensitive Plant Species, Ingalls Human Health and Safety Analysis, and Cultural Resource Compliance for the Environmental Analysis of the Ingalls Treatment Area Report. These reports or memoranda are part of the project record on file at the Beckwourth Ranger District at 23 Mohawk Rd, Blairsden, CA 96103. Copies of these reports are available upon request by contacting the Beckwourth Ranger District at (530) 836-2575.

Fire and Fuels

Introduction

The wildland fuel profile is comprised of accumulated live and dead plant matter arranged in terms of surface fuels, ladder fuels, and canopy fuels. Wildland fuels are characterized by quantity (loading), size and shape, compactness (packing ratio), horizontal continuity and vertical arrangement. These characteristics of wildland fuels can be manipulated to achieve defined modifications of future fire behavior and effects (Pyne & Andrews, 1996; Stephens & Ruth, 2005). This report uses four metrics to gauge the impacts of potential fire behavior and fire effects within the Ingalls Project area. These metrics fall into three main categories:

1. Surface Fuels
   a) Surface Fuel Loading (tons per acre)
   b) Surface /Critical Flame Length (feet)
2. Ladder Fuels
   a) Crown Base Height (ft)
3. Canopy Fuels
   a) Mortality (%)

Specific Methodology

Forest Vegetation Simulator-Fire and Fuels Extension (FVS-FFE) (Reinhardt & Crookson, 2003) as well as Fuels Management Analyst (FMA) software (Carlton, 2005) were used to quantify the effects of proposed vegetation treatments on potential fire behavior and predicted effects. FVS-FFE utilizes previously incorporated fire and fuels methodologies and is a well-established tree and stand growth model that is supported and maintained by the Forest Service. Fuels Management Analyst (FMA) incorporates previously established methodologies and fire models to produce fuel inputs, outputs of potential fire behavior such as fire type, crown fire potential, crown scorch and mortality based on field collected data (Carlton, 2005). The FMA can incorporate field-collected data and import tree list data from the Forest Vegetation Simulator (FVS, 1997); therefore, temporal analysis over time (years or decades) can be done. Common Stand Exam data used for fire modeling were taken directly from the Forest Vegetation Simulator modeling outputs used to assess effects of treatments on forest vegetation (see “Forest Vegetation” section) and imported into FMA.

Affected Environment/Environmental Consequences

Affected Environment

Background

Fire and its periodic occurrence in the Northern Sierra have shaped the succession paths of nearly all terrestrial ecosystems within the Sierra Nevada bioregion. Forests in the Sierra Nevada have been dramatically altered by Euro-American land use practices. Forestlands were logged, grazed, and burned beginning in the mid to late 19th century (Vankat & Major, 1978; McKelvey & Johnston, 1992). A century or more of fire exclusion then followed these activities and a policy of suppressing fire was implemented on lands within the National Forest System. Excluding fire had a profound influence on the structure, function and composition of forest stands and forest landscapes in the most fire-prone forests. Reduced fire frequency in ponderosa pine and mixed conifer forests has created unprecedented accumulations of surface and ladder fuels (Weatherspoon et al. 1996). Higher fuel loads and increased horizontal and vertical continuity of fuels has increased the risk of high intensity fire, including crown fire (Scott & Reinhardt, 2001; Fule, Crouse, & Cocke, 231-248). The accumulation of fuels caused by fire suppression is one of the major causes of the recent increase in the extent and severity of wildfires in the western United States (Arno, 2002). Several recent fires (Boulder Complex 2006, Antelope Complex and Moonlight Fire 2007) north of the project area, where large areas burned at high severity that most likely would not have burned at high severity before the fire suppression period, reflect the increase in fuel accumulation during the last 100 years on the Plumas National Forest. Fuel accumulation associated with past fire suppression within the project area translates to a high fire risk. Additionally, there exist in the project area potential ignition sources including natural causes such as lightning or man-caused sources from highly traveled forest roads to dispersed recreation.

Topography

The Ingalls Project is located along the northwest shore of Lake Davis then continues along the shore of Lake Davis into Grizzly Valley tying into the Freeman DFPZ. It also follows Turner Ridge, which is a prominent ridge that ties into an existing DFPZ (Grizz) and extends into Red Clover Valley connecting to the Red Clover DFPZ. Elevation throughout the Ingalls Project ranges from approximately 5800’ to over 7000’, with proposed treatment occurring primarily on south-southwest facing slopes.

Pre Historic Fire History by Dominant Vegetation Types

Background

This following Section provides a brief description of the past and recent fire history, surface fuels, and fire regimes, as they relate to the Ingalls Project. Fire has been one of the most ecologically important processes in the development of terrestrial ecosystems throughout the northern Sierra Nevada mountain complex (Skinner & Chang, 1996). The direct role of a fire regime in an ecosystem is described in terms of frequency, return interval, spatial extent, magnitude, and seasonality. The spatial patterns and temporal bounds of fire regimes across the landscape are highly variable and are influenced by, but not limited to, climatic oscillations, topography and existing vegetative composition and structure (Moody et al, 2006; Agee J. , 1993, Fites-Kaufman, 1997, Beaty & Taylor 2001, Skinner & Chang, 1996). Proposed vegetation and road treatments would occur primarily within the following vegetation types: eastside pine, Sierra mixed conifer, and white fir forests.

Eastside Pine

There are a limited number of fire history studies that have been under taken in the northern Sierra specifically in the eastside pine vegetation type. Stephens (2001) observed a mean fire return interval of 9 years for a Jeffery pine dominant site east of Yosemite National Park. In addition, Taylor (2004) found an average fire return interval of 11.4 years in mixed Jeffery pine/white fir stands southeast of Lake Tahoe. The most site-specific study done for eastside pine was done approximately 5 air miles from the project area by Moody, Fites-Kaufman & Stephens (2006); this study reported a mean fire return interval of 8 years. Fires in these areas have been characterized as burning with low fire intensity and they perpetuated late seral stages of forest stand development. These studies imply that fire, despite the cause, was a regular and recurring phenomenon into the twentieth century.

Sierra Mixed Conifer

Prior to the twentieth century, the mean fire return interval for the Sierra mixed conifer forest type has been reported as 7 years (range is 1 to 53 years) for the "East Quincy" study plot near the project area (Moody et al, 2006). Other studies have reported fire return intervals in mixed conifer forests in the Sierras as 11.5 years (the range is 1 to 25 years for south-facing slopes) (Beaty & Taylor, 2001) and 4.7 years (the range is 4 to 28 years) (Stephens & Collins, 2004). These studies indicate that low to moderate severity fires, whether human or lightning caused, were a common occurrence in the analysis area into the early 20th century.

White Fir

Successful fire exclusion in the 20th century has created not only a severe fire problem across the West, but has aided in changing species composition over much of the landscape. "Dense thickets of white fir have developed in many sites apparently due to a decreased fire frequency" (Fites-Kaufman et al. 2007). A species composition of shade-tolerant white fir has established on sites that were previously dominated by pine or a more diverse Sierra mixed conifer. Studies have shown the fire-return interval in a white fir forest in the Sierras from 3 to 35 years with an average of 8 years (Skinner & Chang, 1996). This study implies that fire in a white fir site occurred frequently and at a low severity.

Recent Fire History

Historic fires in the Ingalls Project area have been recorded since approximately the 1920's. One large fire, 447 acres in 1937, was recorded within the project area since that time. Human ignition sources exist in the area, these include: highly traveled forest roads, dispersed recreation, and lighting. Fire activity peaks in July through September, with the large fires historically driven northeast from a general southwest wind.

Adjacent Fuels Treatments

Several completed fuels treatments are immediately adjacent to the project area. These projects include the Freeman, Grizz, and Red Clover DFPZ projects.

Environmental Consequences

Alternative 2 – No Action

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Measurement Indicator 1: Effective Fuels Reduction

Fuel Model Metrics: crown base height and mortality

Surface fuels, ladder fuels and canopy fuels would not be modified over the short term. Stand characteristics and predicted potential fire behaviors showed similar trends by CWHR vegetation type over time (Table 15). The predicted density based mortality of suppressed and intermediate size class trees, shedding of lower limbs and needles, and tree growth over time slowly contribute to an increasing live crown base, leading to a slow decrese in canopy fire potential. The predicted direct mortality from scorch and cambial damage does not account for post-fire mortality to fire-damaged trees due to insect and disease activity. Flame lengths remain greater than the desired 4 feet making direct suppression actions likely to be unsuccessful under 90th percentile weather conditions (Table 15). Surface fuel loading remains high thus decreasing efficient productive human and mechanical line construction rates and decreasing the effectiveness of aerial retardant applications. At the landscape level, increased potential for short and long range spotting and the fire's influence on local weather tend to increase erratic fire behavior, resulting in increased fire size with higher tree mortality (Schroeder & Buck, 1970). The above factors would decrease the effectiveness of initial attack by firefighters and extended fire suppression operations, leading to a greater potential for large, high-severity fires.

Table 15. Modeled potential fire behavior outputs for the No-action Alternative (Alt 2).

CWHR Vegetation Type	Treatment Stage	Crown Base Height (ft)	Surface/Critical Flame Length (ft)	Surface Fuel Loading* (tons/ac)	Mortality (%)
Eastside Pine	No Treatment	10	9.9/4.0	20	97
	10 years	11	9.9/4.2	20+	95
Sierra Mixed Conifer	No Treatment	5	9.9/2.5	20	95
	10 years	6	9.9/2.8	20+	93
White Fir	No Treatment	5	9.9/2.5	20	90
	10 years	6	9.9/2.8	20+	90

*Surface fuels greater than 3 inches contribute towards intensity and spotting but are not part of the fire behavior model.

Firefighting Operations and Public Safety

The No-Action Alternative would result in no improvement in fire management's ability to safely suppress and contain fires, both in initial attack and extended fire suppression operations. Fire behavior conditions would not be improved and would continue to decline over time due to continued increases in stand densities and continued surface fuel buildup. Under 90th percentile weather conditions, flame lengths would generally be at least 9 feet (Table 15). The fireline handbook (NWCG, 2004) notes that with 4-8 foot flame lengths "Fires are too intense for direct attack on the head by persons with hand tools. Handline cannot be relied on to hold fire." 8+ foot flame lengths, "Fire may present serious control problems: torching, crowning, and spotting; control efforts at the head will probably be ineffective." (NWCG 2004) (Table 15). Under current heavy surface fuel loadings and high stand densities, the rates of line construction are relatively slow for both hand crews and tractors when compared with the post-treatment desired conditions (Chapter 2). The above factors result in a negative effect on the overall ability of fire managers to safely suppress and contain fires, leading to increased suppression intensity and cost. This increased suppression intensity can lead to a greater potential for resource damage during the fire and higher Burned Area Emergency Response (BAER) Rehabilitation costs after the fire is out. Fire condition classes 2 and 3 would not be modified in the short term. Modifications over the long-term would be primarily caused by high-mortality fires and drought and insect-related mortality.

Measurement Indicator 2: DFPZ Connectivity and Design Placement

Overall, implementation of Alternative 2 would not provide continuity between existing fuel treatments. Under Alternative 2 no connectivity with adjacent DFPZs would occur, reducing their intended effectiveness and leaving a gap in the DFPZ network. Strategic placement of fuel treatments in relation to fire resistant landscape features would also not occur. The road infrastructure allowing access for fire suppression resources would continue to degrade, impacting their ability to efficiently perform suppression activities.

Direct and Indirect Effects of Improving Aspen and Cottonwood Growing Conditions (Alternative 2)

Measurement Indicator 3: Change in Fire Behavior

Aspen regeneration, growth, and development would continue to be suppressed due to shading from conifers. Aspens are fire adapted in the sense that they can regenerate after fire but the individual trees are not fire tolerant. The No-Action Alternative would leave aspen stands susceptible to increased fire severity creating a higher risk of thermal girdling and scorch related mortality. However, in the event of a low or moderate fire there may be a beneficial effect on aspen regeneration, growth, and development by creating open light conditions and disturbed soil post fire.

Direct and Indirect Effects of Providing the Road Access Needed to Meet Project Objectives while Reducing Transportation System Effects (Alternative 2)

Measurement Indicator 4: Changes in access and response time

The current roads in the Ingalls Project area allow for sufficient response times for fire suppression resources.

Cumulative Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

By taking no action, adverse fire behavior is expected to continue resulting in high intensity fires, leading to higher tree mortalities. Over the long term, mortality occurring in high-density stands would continue to increase surface fuel load through deadfall of standing dead trees. This increase in mortality and related deadfall has been witnessed in the Sierra Nevada range as a result of region-wide drought in the late 1980s (Guarin & Taylor, 2005). These increased surface fuels, combined with continuous ladder and canopy fuels, would continue to obstruct suppression effectiveness and would likely maintain stands susceptible to high-mortality fires such as the Moonlight Fire. Increased flame lengths during a wildfire could lead to high mortality in forested areas, RHCAs, PACs, and HRCAs in the project area. In turn, this may result in continued high fire suppression and rehabilitation costs for the indefinite future in the Ingalls Project area. The No-action Alternative would not improve firefighter and public safety, which could lead to potential future injuries or fatalities during wildfire events. The No-action Alternative would also not reduce potential tree mortality or protect rare species and associated habitat from the major adverse effects of severe wildfire (Stephens & Moghaddas, 2005; Agee, 2002). Reasonably foreseeable future projects (Appendix C of the EA) include two active range allotments, a Great Gray Owl habitat treatment unit, Lake Davis Trail Phase 2, Red Clover Poco watershed project, Red Clover Prop 50 watershed restoration project, Blakeless Underburn, Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement, fuel wood and Christmas tree gathering and recreational use. The No-action Alternative would allow stands to continue to develop under the influence of the legacy of past management practices and fire suppression (Agee & Skinner, 2005). Overall, the No-action Alternative would trend conditions for fire behavior and predicted mortality away from the desired conditions described in Chapter 2 of the Ingalls EA.

Under the No-action Alternative no connectivity with existing and future foreseeable adjacent DFPZs would occur, reducing their intended effectiveness and leaving gaps in the DFPZ network. Strategic placement of fuel treatments in relation to fire resistant landscape features would also not occur. The road infrastructure allowing access for fire suppression resources would continue to degrade impacting firefighter ability to efficiently perform suppression activities.

Alternative 1–Proposed Action

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 1)

Measurement Indicator 1: Effective Fuels Reduction

Fuel Model Metrics: crown base height andmortality

Alternative 1 implements fuel reduction treatments reducing surface, ladder and canopy fuels through the use of mechanical thinning, hand thinning and pile burning, grapple piling and pile burning, and underburning. The Alternative 1 tactic of "variable density thinning" with design elements of "structural thinning" in a "clump" and "gap" pattern and "radial thinning" of fire-resilient legacy trees would incorporate silvicultural techniques that are designed to achieve effective fuel reduction and incorporate ecologically important stand and landscape level spatial heterogeneity common in frequent fire adapted forests in the project area (North et al 2009).

Predicted fire behavior and model outputs showed similar trends across all CWHR vegetation types (Table 16). The "variable density thin" treatment targeting the majority of the suppressed and intermediate fire intolerant tree species and "radial thinning" of fire-resilient legacy trees (i.e. Jeffery pine, ponderosa pine, sugar pine and Douglas-fir) in the stand would increase vertical separation and average stand crown base height from 5-10 feet pre-treatment to 13-20 feet post-treatment. The prescribed retention of isolated small diameter trees could be susceptible to scorch related mortality under 90th percentile weather conditions (Stephens & Moghaddas, 2005) even so the overall predicted mortality is considerably decreased following treatments. Damage can be minimized through the use of favorable prescribed fire burning conditions and/or mechanical fuel reduction methods. The proposed treatments show a decrease in the percent of potential mortality from fire related damage that can be expected in the treatment units from a percent probability of 97%-98% mortality to 8%-12% mortality. Horizontal canopy fuel continuity and crown fire spread potential is further decreased due to a clumped tree distribution, where groups of trees are separated by gaps (North, 2009).

Alternative 1 would reduce the surface, ladder, and canopy fuels which in turn increases canopy base height and reduces flame length, resistance to control and the potential for a fire to transition into crown fires. Decreasing crown density may increase surface winds (less canopy to reduce winds before they reach the ground) and surface fuels may be drier (more sunlight reaching the ground) but not noticeably more than under current fuel conditions (Agee & Skinner 2005). It is estimated that Alternative 1 will not open canopies to the extent needed to realize these concerns. It is estimated that in most areas, canopy cover will remain above 30% in the pine types and above 40% in the Sierra mixed conifer and 40 % in white fir in the overstory even after treatment. This change would not be sufficient to change the amount of wind reaching the surface. If full fire suppression continues as the management strategy for unplanned ignitions within the project area, fire suppression resources will have an improved ability to control fires during initial attack with minimized risk to their safety (and the public) and increased ability to keep fires small with the use of direct attack tactics versus indirect tactics. Fires entering the treated stands would typically drop from the crowns to the forest floor, notably changing fire behavior. Aerial firefighting resources would be better able to penetrate the canopy to aid ground resources due to reduced canopy density.

Table 16: Alternative 1 measurement indicators utilized to identify effects and to gauge effective fuels reduction.

CWHR Vegetation Type	Treatment Stage	Crown Base Height (ft)	Surface/Critical Flame Length(ft)	Surface Fuel Loading*(tons/ac)	Mortality (%BA)
Eastside Pine	Pre-Treatment	10	9.9/4.0	20	97
	Post-treatment	20	0.8/6.4	5.5	8
	10 years	26	1.5/7.7	6.8	7
Sierra Mixed Conifer	Pre-Treatment	5	9.9/2.5	20	97
	Post-treatment	13	0.8/4.8	5.5	10
	10 years	21	3.0/6.6	6.8	9
White fir	Pre-Treatment	5	9.9/2.5	20	98
	Post-treatment	17	0.8/5.7	5.5	12
	10 years	23	3.0/7.0	6.8	11

*Surface fuels greater than 3 inches contribute towards intensity and spotting but are not part of the fire behavior model.

Design features used to minimize fire effects and/or retain habitat structures preferred by wildlife species such as; grouping of larger trees, juniper retention, and structural diversity patches will have lower potential for loss since they would not be continuous and would allow for more effective fire suppression. This would be similar to the variability in forest conditions produced by frequent fire (North et al, 2009).

In utilizing mechanical treatments, stand structures are modified quickly and more precisely than with prescribed fire alone (North et al, 2009). Under this alternative, treatments are effective in breaking up the horizontal and vertical continuity of live fuels in the lower canopy layers and/or in effect pre-treating the stands to more readily allow prescribed fire to be re-introduced. Silvicultural cuttings can only partially substitute for fire (Weatherspoon, 1996). This alternative allows increased potential to utilize prescribed fire as either a maintenance treatment and/or in conjunction with mechanical treatments as a follow-up process to achieve forest resilience. Prescribed fire could mimic the natural ecosystem functions of frequent low-to-moderate severity fire (Weatherspoon, 1996).

Underburning is the proposed treatment method for units under several conditions. Certain units meet the desired condition from the standpoint of tree density and therefore do not need thinning and can safely be burned. Other units are primarily on steeper slopes with low tree density and not available for mechanical harvest, but can safely be underburned to reduce surface fuels to meet desired condition. Follow up surface fuels treatments would substantially diminish existing and activity generated surface fuels and potential fire behavior compared to current conditions.

Units meeting desired conditions would not be burned, thereby decreasing total burned acres and emissions. Due to operational constraints underburning and pile burning would be conducted over a 5- to 10-year period. During this lag time of treatment, surface fuels could increase to higher than pre-treatment levels, however this potential increase is not expected to increase fire behavior and risk beyond what would occur under current conditions.

The project proposes the use of whole tree harvesting which does not add significant amounts of activity generated fuels and minimizes additional fuel accumulations in the treatment areas. This modification to the surface fuel loading was accounted for in the fuel model selection assigned to the pre-treatment, post-treatment, and 10-year post-treatment environments. Surface fuel loading decreased significantly across all vegetation types to an average of approximately 5 to 8 tons an acre. The reductions in surface fuels may be achieved through a variety of treatments including grapple piling, mastication, hand piling, underburning and pile burning. It is estimated that surface fuel loading would directly influence the potential flame lengths and fireline intensity in the post-treatment environment by more than half allowing for increased line production rates for fire suppression personnel.

Mastication, Grapple Pile and Hand Thinning

Grapple piling of shrubs is more effective than mastication as it pulls the shrubs up by the roots, decreasing the amount of shrub regeneration in an area. Once the piles have been burned, grapple piling removes fuel from the area, thus lowering fire effects and decreasing the time it takes fire personnel to suppress and control fire in the treatment area.

While mastication does not actually remove fuel from the area, it does rearrange the structure from a vertically oriented fuel structure (ladder fuel) to a horizontal fuel structure thus lowering fire effects and decreasing the time it takes fire personnel to suppress and control fire in the treatment area. Mastication would be used where feasible to effectively reduce surface and ladder fuels, by rearranging the vertical and horizontal structure of the fuel on the landscape.

Firefighting Operations and Public Safety

The proposed modifications under this alternative to the surface, ladder and canopy fuel portions of the Ingalls Project fuel profile would enhance the ability of firefighting personnel to safely manage and engage in suppression actions in the event of a wildfire. This is particularly true of fires that start in areas receiving fuel treatment or in areas where fires have the potential to initiate in fuel treatments. Due to the strategic placement of the treatment units and National Forest System roads, conditions would allow for safe ingress and egress for fire personnel, equipment and public land users should a wildfire affect these areas. Greater amounts of aerial retardant would penetrate the dominant overstory canopy and reach the surface fuels slowing the forward combustion of fuels in the treatment areas. The proposed mechanical thinning, hand thinning, mastication, and grapple piling units would result in a marked improvement to potential fire behavior and effects related to firefighting operations and public safety.

Measurement Indicator 2: DFPZ Connectivity and Design Placement

This alternative would provide connectivity with existing adjacent DFPZs (Grizz, Freeman, and Red Clover), increasing their intended effectiveness and tying together existing gaps in the DFPZ network. Strategic placement of fuel treatments in relation to fire resistant landscape features, such as rock outcrops, would further increase the effectiveness of the fuel treatment. The proposed improvements to road infrastructure would allow efficient access for fire suppression resources increasing their ability to efficiently perform suppressive actions.

Direct and Indirect Effects of Improving Aspen and Cottonwood Growing Conditions (Alternative 1)

Measurement Indicator 3: Change in Fire Behavior

Fire exclusion has permitted conifers to encroach into aspen stands, thereby competing with existing aspen and creating shade conditions unfavorable for aspen regeneration, growth, and development. Conifer in-growth has also contributed to fuel ladders within aspen stands, increasing susceptibility to severe fire. The majority of conifers less than 30 inches in diameter would be removed to eliminate conifer encroachment. This would have a beneficial effect on aspen regeneration, growth, and development by creating disturbed soil and open light conditions, as well as reducing potential fire severity and aspen mortality in the event of a fire. Aspens are fire adapted in the sense that they can regenerate after fire but they are susceptible to thermal girdling and scorch related mortality. However, healthy aspen habitats are highly mesic sites, producing higher fuel moisture content than adjacent habitat, which can reduce adverse fire behavior.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects (Alternative 1)

Measurement Indicator 4: Changes in access and response time

The proposed improvements to road infrastructure would allow efficient access for fire suppression resources increasing their ability to efficiently perform suppression activities. Additionally, the road improvements will aid in faster response times for fire suppression resources.

Cumulative Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 1)

The activities listed in Appendix C of the EA, that can be expected to be implemented include two active range allotments, a Great Gray Owl habitat treatment unit, Lake Davis Trail Phase 2, Red Clover Poco watershed project, Red Clover Prop 50 watershed restoration project, Blakeless Underburn, Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement, fuel wood and Christmas tree gathering and recreational use. Recreational activities near the project area include the Lake Davis Lighting Tree Campground and dispersed camping, hunting, fishing, hiking, mining and OHV use. All of these activities are likely to contribute to possible future ignition sources in the project area. The trend of increased human ignitions is predicted to increase in the Ingalls Project area (Stephens, 2005). The implementation of Alternative 1 would minimize the potential for these ignitions to grow into large-scale destructive wildfire and would enhance fire management's ability to contain, control and suppress wildfires in the Ingalls Project area.

Cumulatively the implementation of Alternative 1 will provide more fuel reduction treated acres that can perform as an anchor point for further future treatments enhancing and increasing the connectivity of treatments across the landscape. Previously thinned DFPZ' s including Grizz, Freeman, and Red Clover will continue to be evaluated for required surface fuel work either done in the form of mastication, grapple piling, pile burning or underburning to meet the surface fuel desired conditions set in the environmental analysis associated with each project. These treatments will continue to be adjacent to NFS road infrastructure and will connect to fire resistant landscape features.

DFPZ Maintenance within the Ingalls Project

In July of 2003, a ROD was signed for the HFQLG FSEIS. It documented the results of an environmental analysis of the effects of alternative management strategies for maintenance of DFPZs within the HFQLG Pilot Project area. The HFQLG FSEIS and ROD, in combination with the original HFQLG Act FEIS and ROD, provide programmatic guidance for DFPZ construction and maintenance in the HFQLG Pilot Project area. The HFQLG FSEIS ROD calls for consideration of all practicable methods of vegetation control for site-specific projects.

If hand thinning, grapple pile or mastication option is implemented and does not achieve DFPZ objectives for desired condition in all treatment units; an underburn would be used as a follow-up treatment to meet short-term objectives. In the long term, the foreseeable maintenance of the DFPZ would consist of prescribed fire, mechanical or hand treatments. Specific maintenance treatments would be determined based on site-specific analysis of land allocations, slope, vegetation types, and previous underburn treatments.

The Forest Service would assess the need for DFPZ maintenance treatments approximately five to ten years after the completion of the initial mechanical and fire activities proposed in the Ingalls Project. It is expected that maintenance activities would take place as described in the HFQLG FSEIS and further refined by on-site information available at the time that maintenance would be proposed. Specific decisions about maintenance for particular DFPZ (timing of entry and treatment method) would be made at the time DFPZ maintenance is deemed necessary (HFQLG FSEIS, page 3).

Climate Change Considerations

Forests play a major role in the carbon cycle. The carbon stored in live biomass, dead plant material, and soil represents the balance between CO2 absorbed from the atmosphere and its release through respiration, decomposition, and burning. Over longer time periods, indeed as long as forests exist, they will continue to absorb carbon. Complete quantifiable information about project effects on global climate change is not currently possible and is not essential to a reasoned choice among alternatives. However, based on climate change science, the relative effects of these treatments on the ecosystem carbon cycle are recognized. The positive long-term effects on the carbon cycle of proposed fuel reduction treatments are a good example of this. Given the anticipated increase in large wildfires in California (Calif. Climate Action Team 2009), the action alternatives propose beneficial fuel reduction treatments which could contribute to reducing or limiting emissions, size, and intensity of potential future wildfires.

In addition, action alternatives that implement treatments which meet desired conditions for forest health would enhance growth of large residual trees, reduce stand densities, and improve stand and landscape resiliency to forest disturbances such as insect outbreaks greater than endemic levels and large scale high severity fire, thereby enhancing the potential for carbon sequestration within the project area. These treatments would have long-term beneficial indirect effects which would contribute to beneficial cumulative effects on air quality.

Alternative 3 – Non-commercial Funding

Direct and Indirect Effects of DFPZ Fuels Reduction Treatments (Alternative 3)

Measurement Indicator 1: Effective Fuels Reduction

Alternative 3 the Non-commercial Funding Alternative, implements fuels treatment focused on reducing surface, ladder and canopy fuels through the use of mechanical thinning, hand thinning and pile burning, grapple piling and burning, and underburning. Under this alternative, thinning from below, through biomass, pre-commercial and/or commercial means, would focus first on the smaller trees for removal and moving through the lower canopy levels until an upper diameter limit (UDL) (Table 17) is reached. Predicted fire activity would be reduced to a low severity fire due to the treatment's reduction of surface, ladder, and crown fuels.

Table 17 Upper Diamerter Limits for stands under the Non-Commercial Funding Alternative

Stand Type	Upper Diameter Limit (UDL) inches	Stand Type	Upper Diameter Limit (UDL) inches
EPN3D	8	SMC3M	14

EPN5P	8	WFR3P	8
SMC2M	10	WFR4M	12
SMC3D	14	WFR4P	8

Treatments would result in stands that are typically uniform with trees evenly spaced and possibly an undesired species composition. Treatments in Alternative 3 would increase canopy base height and decrease crown density. Predicted fire behavior and model outputs showed similar trends across all CWHR vegetation types (Table 18). "Thinning from below" substantially increases average stand crown base height (CBH) from an average of about 7 feet pre-treatment to 13 feet in the post-treatment environment,decreasing the likelihood of transition of surface fire to crown fire behavior under a 90th percentile or greater weather event. The proposed treatments show a decrease in the percent of potential mortality from fire related damage that can be expected in the treatment units.

The project proposes the use of whole tree harvesting which does not add significant amounts of activity generated surface fuels and minimizes additional fuel accumulations in the treatment areas. The modification to the surface fuel loading was accounted for in the fuel model selection assigned to the pre-treatment and post-treatment environments, and was decreased across all vegetation types to approximately 5 tons an acre. The reductions in surface fuels can be achieved through a variety of treatments including grapple piling and burning, mastication and underburning. Surface fuel loading directly influenced the potential surface and critical flame lengths that would be expected to be experienced in the post-treatment environment. The reductions in surface fuel loading also decreased surface fire flame lengths by more than half allowing for increased line production rate for fire suppression personnel and equipment.

The proposed modifications to the surface, ladder and canopy fuel portions of the Ingalls Project fuel profile in this alternative would enhance the ability of fire fighting personnel to safely manage and engage in suppression actions in the event of a wildfire in the project area. This is particularly true of fires that start in areas receiving fuel treatment or in places where fires would impact the fuel treatments. Due to the strategic placement of the treatment units, evacuation and movement corridors would increase safe ingress and egress for fire personnel, equipment and public land users should a wildfire impact these areas. Greater amounts of aerial retardant would penetrate the over story canopy and reach the surface fuels slowing the forward combustion of fuels in the treatment areas.

Table 18 Alternative 3 measurement indicators utilized to identify effects and to gauge effective fuels reduction.

Dominant Vegetation Type	Treatment Stage	Crown Base Height (ft)	Surface/Critical Flame Length (ft)	Surface Fuel Loading* (tons/ac)	Mortality (%)
Eastside Pine	Pre-Treatment	10	9.9/4.0	20	97
	Post-treatment	15	0.7/5.2	2.71	6
	10 years	18	1.3/5.9	5.5	5
Sierra Mixed Conifer	Pre-Treatment	5	9.9/2.5	20	98
	Post-treatment	14	0.7/5.0	7.63	6
	10 years	17	1.3/5.7	5.5	5
White Fir	Pre-Treatment	5	9.9/2.5	20	98
	Post-treatment	10	0.8/4.0	5.5	7
	10 years	16	1.5/5.2	5.5	5

*Surface fuels greater than 3 inches contribute towards intensity and spotting but are not part of the fire behavior model.

Measurement Indicator 2: DFPZ Connectivity and Design Placement

Under the Non-commercial Alternative connectivity with adjacent DFPZs would occur, increasing their intended effectiveness and tie together existing gaps in the DFPZ network. The proposed improvements of road infrastructure would allow efficient access for fire suppression resources increasing their ability to efficiently perform suppression activites.

Direct and Indirect Effects of Improving Aspen and Cottonwood Growing Conditions (Alternative 3)

Measurement Indicator 3: Change in Fire Behavior

There would be no treatment done to aspen stands in this alternative and would thus have the same effect as Alternative 2.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects (Alternative 3)

Measurement Indicator 4: Changes in access and response time

Alternative 3 proposes no change to the current road infrastructure. The current roads in the Ingalls Project area allow for sufficient response times for fire suppression resources.

Cumulative Effects of DFPZ Fuels Reduction Treatments (Alternative 3)

The implementation of Alternative 3 would enhance fire management's ability to contain, control and suppress wildfires spreading from private lands onto public land especially where they impact fuel treatment units thus decreasing the potential for a large scale high severity fire in the Ingalls Project area. Recreational activities in the project area include the daily recreational use of OHV's, hiking, camping, mining and hunting which are likely to contribute as possible future ignition sources in the project area. The potential for human ignitions is predicted to increase in the Ingalls Project Area (Stephens, 2005). The implementation of Alternative 3 minimizes the potential for fire ignitions to grow into large scale destructive wildfire in areas of the proposed fuel treatments.

Surface Fuels

Surface fuel treatments would have the same effect as Alternative 1.

Mastication, Grapple Pile and Hand Thinning

Mastication, grapple piling and hand thinning Surface fuel treatments would have the same effect as Alternative 1.

Firefighting Operations and Public Safety

Firefighting operations and public safety would receive the same benefits as Alternative 1.

Air Quality

Introduction

The Ingalls Project area is located in Plumas County, California. Nearby towns, communities, and highways are shown in Table 19. Prescribed fire is one of the primary activities proposed for the Ingalls Project that would have a direct impact on air quality. Underburning would be conducted during fall, spring, or winter—the most favorable times in terms of smoke dispersion. The entire project area is contained in the Northern Sierra Air Quality Management District (NSAQMD) within the Mountain Counties Air Basin. Air quality in the context of this document refers to the amount and type of emissions contained in smoke produced by prescribed burning and wildfires. Particulate matter is of the greatest concern as particulate emissions in smoke can affect both visibility and human health.

Air quality can be severely impacted by particulate matter and other pollutants during large wildfire events. Impacts from the 1992 Pendola fire on the Plumas and Tahoe National Forests affected air quality 60 miles away in Sacramento, California. Fugitive dust caused by construction and use of unpaved roads can produce PM_{10} in quantities great enough to impair the visual quality of the air. These effects are localized and can be mitigated by effective dust abatement methods. Dust generated by skidding, loading, and site preparation activities also contributes to fugitive dust; however, the level contributed by these activities is unknown.

Table 19. Towns, communities and highways in the vicinity of Ingalls Project

Town or Feature	Distance and Direction from Ingalls Project Boundary
Blairsden	10 miles south
Graeagle	11 miles south
Mabie	9 miles south
Clio	13 miles south
Quincy	16 miles west
Portola	8 miles south
Highway 89	10 miles south
Highway 395	16 miles East
Highway 70	8 miles south

Specific Methodology

The predicted emissions from wildfire, prescribe fire and harvest activities in the proposed project area have been estimated using emission factors from EPA Document 42 and from the National Environmental Policy Act Air Quality Desk Reference Guide (CH2M Hill 1995; table 3.3.2-1 for timber harvest operations). Prescribe fire would be done over a period of five years; the amount of particulates is based on ~3,300 acres proposed for treatment. The prescribed fire would be done in the spring, fall, or winter months because these are the best times of year for dispersion.

Each year the burning would take place over a period of months, with treated areas spread throughout the project area.

Affected Environment/Environmental Consequences

Affected Environment

The air quality attainment status for ozone, carbon monoxide, sulfur dioxide, and other compounds is listed in Table 20. The attainment status was derived directly from the NSAQMD "Annual Air Monitoring Report" (2005).

Table 20. Attainment designations for Plumas County.

Compound	National Attainment Status	State Attainment Status
Ozone (1 hour)	Attainment	Unclassified
Ozone (8 hour)	Attainment	Not applicable
Carbon monoxide	Attainment	Attainment
Nitrogen dioxide	Attainment	Attainment
Sulfur dioxide	Attainment	Attainment
PM_{10}	Unclassified	Nonattainment
$PM_{2.5}$	Unclassified	Nonattainment – only the Portola Valley is in non-attainment for the state $PM_{2.5}$ annual standard

Source: NSAQMD (2004)

Currently, Plumas County is in nonattainment status for particulate matter $(PM)_{10}$ (county wide) and $PM_{2.5}$ (Portola only). The Project Area is less than 8 miles northwest of Portola at its closest point. According to the NSAQMD 2005 report, the major contributors to both PM_{10} and $PM_{2.5}$ levels include forestry management burns, woodstoves, residential open burning, vehicle traffic, and windblown dust. These problems can be relieved or made worse by local meteorology, winds, and temperature inversions. In addition, large areas in and adjacent to local communities can be heavily impacted by smoke for extensive summer periods (several weeks) due to wildfire such as in the 3,500-acre Stream fire, 3,000 acre Boulder fire, and the Antelope Complex and Moonlight fires. The main community of Portola is subject to strong inversions and stagnant conditions in the wintertime. Those conditions, coupled with intensive residential wood burning, can result in very high episodic $PM_{2.5}$ levels (NSAQMD 2005). Levels of PM_{10} have been greatly decreased due to a reduction of non-EPA (Environmental Protection Agency) approved woodstoves in existing residences.

Current sources of particulate matter from the project area include smoke from large wildfires, smoke from underburning and pile burning, emissions and dust from standard and off-highway vehicles, dust and emissions from harvest activities occurring on private lands, smoke from campfires, and wind-generated dust. The amount and duration of these emissions vary by season, with most emissions from wildfires, timber harvest, and recreational activities occurring between

May and late August, and emissions from prescribed burning occurring from late October through mid-April.

Environmental Consequences

Alternative 2–No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Under this alternative, no increase in ozone precursors or PM_{10} emission levels would be produced from prescribed burning of activity-generated fuels, harvest operations, or understory burning. Alternative 2 would not result in a reduction of surface fuels, so the potential for substantial degradation of air quality from future wildfire would not be reduced. Air quality can be severely impacted by particulate matter and other pollutants during large wildfire events. Impacts from the 2007 Moonlight fire on the Plumas National Forests affected air quality over 100 miles away. The No Action Alternative would not provide any opportunities for reducing existing forest fuels and the hazard they pose in wildland fires. During the flaming phase of a stand-replacing wildfire, air quality degradation can exceed federal and state standards hundreds of miles downwind. The potential ozone precursors from a wildfire are shown in Table 21.

Table 21 Potential ozone precursors and PM10 from wildfire emissions.

	Acres (range)	CO (tons)	Nitrogen Oxides (tons)	Volatile Organic Compounds (tons)	PM10 (tons)
Wildfire	1,000-5,000	1050-5250	30.0-150.0	179.1-895.50	127.50-637.50

Cumulative Effects

Under Alternative 2, the project area would be subjected to long-term deposition of surface fuels. Forest fuels would continue to increase with biomass production and would out-produce the decomposition rates in this climate. The long-term chronic effects of wildfires would be higher PM_{10} emissions, mostly due to large areas of exposed soil and ash in the aftermath of a high-intensity wildfire. Without considering the possibility of future wildfires, the No Action Alternative would have no cumulative effects on particulate matter and visibility.

Alternative 1 – Proposed Action

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction, Aspen and Cottonwood and Road Treatments (Action Alternatives)

The predicted criteria pollutant totals for timber operations (emissions from trucks and other equipment) would vary according to the acres of treatments performed each year. Table 22 presents the total criteria pollutants for prescribed burning, timber operations, and roadwork activities.

Table 22 Criteria pollutant totals for timber operations and prescribed burning combined for Alternative 1.

	Acres	CO (tons)	Nitrogen Oxides (tons)	Volatile Organic Compounds (tons)	PM10(tons)
Underburning only or Hand thin/underburn	1123	1126.32	8.98	50.95	116.21
Mechanical equipment for fuels reduction and road work	2201	7.72	13.89	1.04	1.03
Pile burning	2035	749.19	20.35	36.45	80.99
Criteria pollutant totals	3323	1883.23	43.22	88.44	198.23

In the event of a wildfire, the stands in the Ingalls Project area that are treated would have less material to burn producing less particulate matter emissions than untreated areas outside the project area.

Pile burning could produce more particulate matter per acre than understory burning because the standing biomass would be cut and piled, producing higher surface fuel loads. However, piled material is allowed to cure and can be ignited with lower fuel moistures, which ensures complete and efficient consumption and less particulate matter being produced. If fuel loading does not meet the desired condition after the biomass reduction is complete than an understory burn is prescribed, this is predicted to produce fewer emissions because of the lighter fuel load.

The release of particulate matter into the air during prescribed burning can have adverse effects on visibility and public health. As described above, the volume of particulate matter is related to which burning method is used and the extent of the burning. Particulate concentrations in the Mountain Counties air basin are influenced by climatic conditions and other emission-generating activities carried out in the air basin. Particulate concentrations are regulated through compliance with the California Air Resources Board and Northern Sierra Air Quality Management District.

The prescribed burning proposed in the action alternatives would be used to reduce fuel loadings to an acceptable level. Under favorable smoke-dispersal conditions, the smoke would likely affect air quality during ignition and for approximately three days following ignition. Another impact of the action alternatives would be the emissions and dust caused by project activities. Fugitive dust caused by the use of unpaved roads can produce PM_{10} in quantities great enough to impair the visual quality of the air. These effects are localized and would be mitigated by adherence to dust abatement standard operating procedures. Emissions from burning and equipment used for other project activities (such as thinning) may be occurring at the same time, which would elevate particulate matter. By following the burn plan and Air Quality Management District requirements for burning and managing other project activities, it is unlikely that emissions caused by the project would exceed California Air Quality Standards for the Air Quality Management District.

Cumulative Effects (Proposed Action)

The VOC, NO_x, and PM_{10} emissions from the action alternatives would contribute to particulate matter loading locally. Local effects include cumulative emissions from prescribed burning resulting from past practices, natural surface fuel buildup, and activities on federal, state, and private lands near the Ingalls Project area. The $PM_{2.5}$ atmospheric concentrations currently do not exceed national standards; however, emissions could exceed California Air Resources Board (CARB) standards if (1) weather conditions predicted by CARB meteorologists do not prevail, or (2) emissions do not disperse as predicted, and/or (3) emissions from other Air Quality Management District's adversely impact air quality in local districts. Forest Service and CARB smoke-dispersal forecasting would be used as part of the burn plan to mitigate effects within the regulatory framework.

The cumulative effects analysis for Air Quality considers ongoing, proposed and reasonably foreseeable future actions. Impacts to air quality from prescribed underburning and machine pile burning in the project and adjacent areas, during the last five years have been minimal and no Notice of Violation of air quality standards has been issued to the Plumas National Forest during this period. The action alternatives would not increase the amount of prescribed fire activities in the area above what has been implemented for the last five years, and would not impact the air quality of the area when combined with ongoing and reasonably foreseeable future actions. The action alternatives would have cumulative effects on air quality in the project area and local air basin (Northern Sierra), but the effects would be managed to be within the regulatory standards of the California Air Resources Board. The dust and emissions from project activities would be mitigated by requiring that Standard Operating Procedures be included with timber sale or service contract packages.

Alternative 3 (Non-commercial)

Direct and Indirect Effects of DFPZ fuels and Road Treatments (Action Alternatives)

The predicted criteria pollutant totals for timber operations (emissions from trucks and other equipment) would vary according to the acres of treatments performed each year. Table 23 presents the total criteria pollutants for prescribed burning, timber operations, and roadwork activities with Alternative 3.

Table 23 Criteria pollutant totals for timber operations and prescribed burning combined for Alternative 3.

	Acres	CO (tons)	Nitrogen Oxides (tons)	Volatile Organic Compounds (tons)	PM10(tons)
Underburning only or Hand thin/underburn	1123	1126.32	8.98	50.95	116.21
Mechanical equipment for fuels reduction and road work	1507	1.63	3.53	0.29	0.27
Pile burning	1341	493.69	13.41	24.02	53.37

Criteria pollutant totals	2630	1621.64	25.92	75.26	169.85

In the event of a wildfire, the stands in the Ingalls Project area that are treated would have less material to burn producing less particulate matter emissions than untreated areas outside the project area, when compared to Alternative 2. However because more material would be left than with the Proposed Action, and because less acres would be treated, if a wildfire were to occur after the implementation of Alternative 3 it would likely produce higher emissions than the same fire under Alternative 1.

Cumulative Effects

Cumulative effects would be similar to those described for Alternative 1.

Forest Vegetation

Introduction

This assessment addresses how the different alternatives impact forest vegetation, as measured by stand density (basal area or stand density index, and indirectly crown canopy cover), stand composition (trees per acre by species), and stand structure (trees per acre by diameter class,). These measurements are correlated to appropriate stocking levels, and stand conditions to maintain stand growth and health, including resistance to epidemic levels of insects and disease. This document also addresses current and desired stand conditions and the silvicultural treatment options for improvement of aspen habitat found in the project area.

Analysis Methodology

This analysis used five primary sources for the fundamental vegetative analysis and assessment; a 2008 digital ortho-photographic layer associated with the Geographic Information System (GIS), a 2010 digital California Wildlife Habitat Relationship (CWHR) vegetation layer, field reconnaissance of the project area, stand exam sampling of random stands stratified by vegetation type, and the previous fire history of the area.

Field reconnaissance and common stand exam (CSE) data was collected by Beckwourth staff. CSE data collected was based on stands identified and digitized using the 2008 digital orthographic-photographic layer. Also used in this process was the CWHR vegetation digital layer, which subdivides the forest's vegetation into CWHR vegetation types. CWHR vegetation types are discussed further in this report under the "Affected Environment" Section, as well as in the Silviculture Specialist Report. Vegetative stands within the project area were randomly sampled to determine forest vegetative characteristics for each sampled stand. These sampled stands were post-stratified into corresponding CWHR vegetation types for analysis of the Ingalls Project. Not all CWHR types were sampled, but were stratified into common sampling types. This was done because of the number of stands within the vegetation types not sampled were minor or did not exist within the treatment designated DFPZ classifications. CWHR types not sampled were assigned to similar types that were sampled for this project. Collected stand level and tree measurement inventory data was processed for input into a computerized forest growth model named the Forest Vegetation Simulator (FVS). Once data was input, existing stand conditions could be modeled into the future using this software tool. For more details concerning methodology, see Silviculture Specialist Report.

Aspen Surveys

Aspen stand surveys on more than 550 stands, totaling approximately 1,100 acres were conducted in 2004. The Region 5 Aspen Stand Assessment protocol developed for the Aspen Delineation Project (ADP 2002) was used as the sampling procedure. Based on these assessments, each aspen stand was assigned a stand loss risk factor rating of none, low, moderate, high or highest (ADP 2004). To enhance the ADP surveys a sampling of aspen stands was part of the CSE vegetation sampling within the Ingalls project. Because the aspen stands have started a conversion to SMC vegetation types,these stands are currently classified as CWHR type SMC2M under the Ingalls sampling stratification.

Affected Environment/Environmental Consequences

Affected Environment

Description of the Vegetative Landscape

The Ingalls Project area has been delineated into habitat types as classified by the California Wildlife Habitat Relationships (CWHR) guidelines (Mayer and Laudenslayer 1988). CWHR habitat types have been developed for the State of California to classify vegetation throughout the state. This classification system has been adopted by the Plumas National Forest to classify its vegetation. While 27 habitat types are found within the Ingalls Project area, only 12 vegetation habitats are represented within areas proposed for treatment. Table 24 shows the acres associated with the entire project area, as well as a cross sectional look at the potential DFPZ and Area Thin acres proposed for treatment under the Proposed Action alternative. This should give the reader a representation of overall project CWHR acres to those potentially being treated.

Table 24: Acres of habitat type within the Ingalls Project Area

California Wildlife Habitat Relationship (CWHR Type) (Grouped)	Ingalls Project Area		DFPZ/Area Thin	
	Acres	Percent	Acres	Percent
Sierra Mix Conife (SMC)r	7,945	44.5%	1,341	32.7%
Eastside Pine (EPN)	5,148	28.8%	1,725	42.1%
Fir Types (White/Red Fir)	2,105	11.8%	61	1.5%
Montane Hardwood/Riparian	128	0.7%	40	1.0%
Montane Chaparral/Shrub	1,438	8.1%	577	14.1%
Grassland	628	3.5%	151	3.7%
Wet Meadow/Wetland	337	1.9%	179	4.4%
Miscellaneous	129	0.7%	21	0.5%
Total	**17,858**	**100%**	4,095	100%

As the table displays, there is a large shift in percentages between overall acres to those potentially being treated (i.e. eastside pine from 29% to 42%). DFPZ units would primarily be at locations that support defensive positions in fighting wildland fire, which includes primarily ridge tops and south slopes with non-forested vegetation, or comprise of EPN or SMC vegetation types. This explains the percentage shift in the CWHR acres being treated.

A majority of the project’s forest vegetation can be described as mid-mature to late-mature (CWHR size class 4) forest with moderately dense or dense over-story layers (CWHR crown class of M or D). Jeffery pine, ponderosa pine, sugar pine, lodgepole pine, white fir, and incense cedar dominate the over-story. White fir, ponderosa pine and Jeffrey pine dominate the understory, except in SMC vegetation types where incense cedar is also prevalent. The mix of these species varies from stand to stand. The presence of pine and incense cedar suggests a natural fire regime, which consists of frequent low intensity spreading fires. Several 15-20-year-old plantations from previous projects are scattered throughout the project area. Shrub layer density varies in intensity from a moderate to light cover. Moderate density levels are in younger, open, north aspect stands where as light densities are scattered throughout heavily stocked, south facing stands. Past wildfire has not had an influence on the brush component, except in isolated areas where small fields of brush containing primarily manzanita and/or snowbrush exist in proximity or within openings of forested stands. Plantations at higher elevations have tree species growing up through brush, but this varies widely. Lower elevation plantations do not have a large brush component, mainly due to past treatment or growth limiting resources. The herb layer is comprised of scattered dry and moderate site indicator species. The vegetation is primarily heterogeneous, with existing stand structures and tree species composition reflecting past harvest activities, stand replacing wildfires and fire exclusion.

Current tree mortality can be attributable to insects and disease and has been found to be patchy within the project area. Most of the mortality is at endemic levels and is present throughout all species. Aerial surveys (USFS, PSW 2010) of the project area have detected increases in mortality over the past several years. This increase in mortality is strongly associated to a period of below normal precipitation and high stand densities in the project area (FHP Report 2010).

Stand Density and Structure Composition

Species Composition

Ingalls CSE plot data was stratified into vegetative types within this analysis area, east-side pine (EPN), Sierra mixed conifer (SMC) and white fir (WFR). Figure 2, Figure 3, and Figure 4 show the results of this analysis. Each figure contains two separate pie charts one showing species composition by basal area (BA) and the other by trees per acre (TPA). The data indicates that shade-tolerant species are invading shade-intolerant stand types. For example, looking at Figure 2 we see an increase in the percentage of white fir within the TPA graph versus the BA graph. This indicates that white fir is showing up as smaller diameter trees, therefore an understory invader. If the white fir component had been larger in diameter, the percentage under the TPA graph would have been retained. Since basal area is influenced more by larger trees, the small white fir are not well represented in overall basal area; however, under the trees per acre chart the small trees are represented indicating regeneration of white fir within the vegetation type.

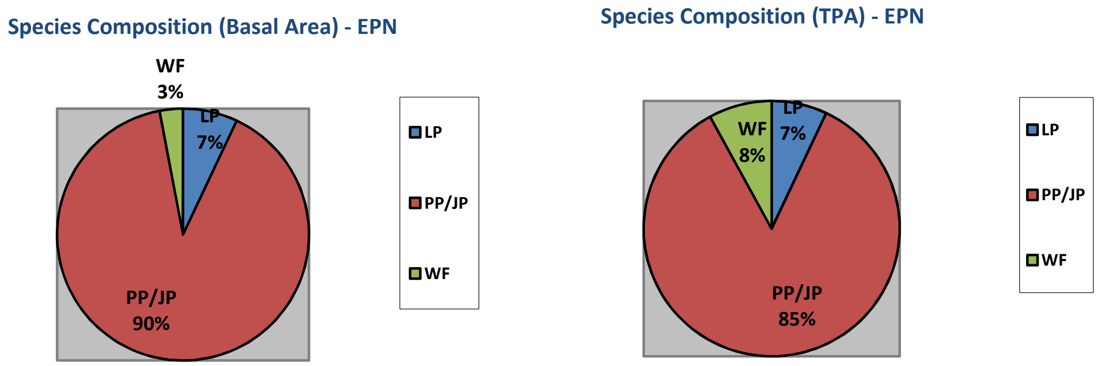

Figure 2: Species Composition – Eastside Pine

In Figure 3, species composition for the SMC vegetation type, this phenomenon is happening for incense cedar as well as white fir. This is even more dramatic than the EPN vegetation types. The incense cedar percentages differ from 24% to 15% for TPA versus BA, while white fir differs from 50% to 35% respectively.

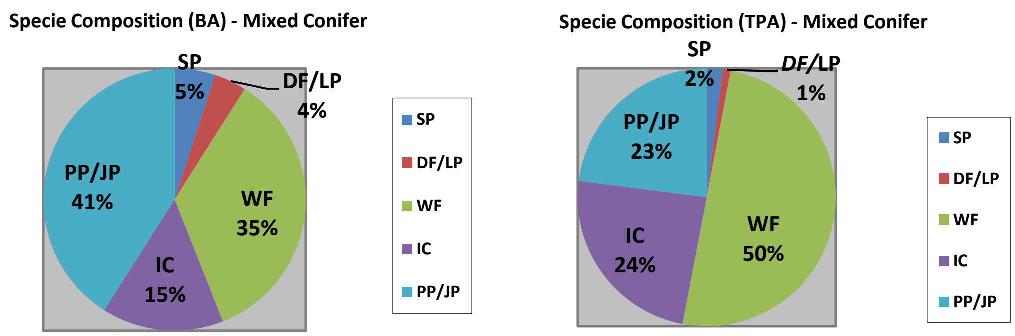

Figure 3: Species Composition – Sierran Mixed Conifer

Looking at the fir vegetation type (Figure 4), this change does occur slightly within the white fir, but only because lodgepole is being represented by a very large tree diameter component. White fir is such a large composition of the stand that any big differences in species represented as a small percentage will alter the species with a large representation. In this case, only 12 of every 100 trees is represented by a species which is not white fir, however the 12 trees, represented by both ponderosa pine and lodgepole pine, on average are much larger than the fir, thus they have a large influence on overall stand basal area. This indicates that the pine species have a significant influence on basal area composition within the fir types, thus must be a major consideration in assessment of treatment options.

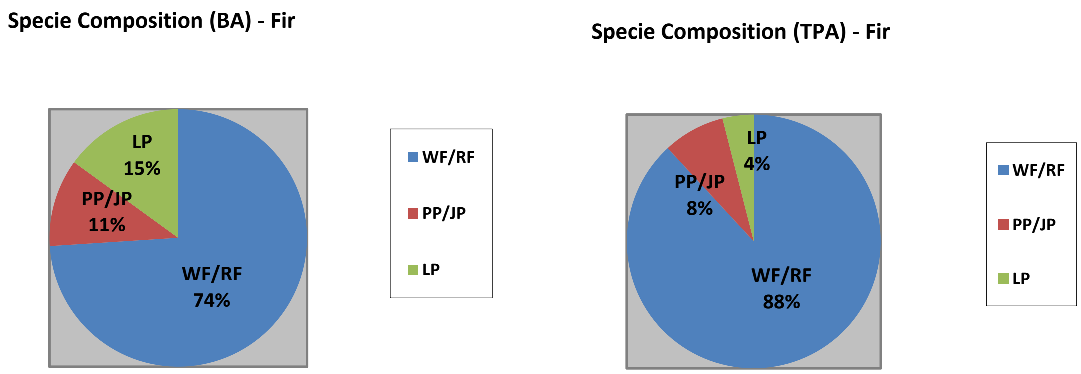

Figure 4: Species Composition – Fir

Vegetation Size and Distribution

The predominant size class within the Ingalls Project area, under the CWHR typing system, is size class 4. Approximately 55% of the timber stands being treated fall within the 11 to 24 inch diameter class, as compared to an overall percentage of 68% within the project area. Fifteen percent of the landscape within the Ingalls project area contains vegetation, which is not forested (i.e. grassland, meadow, chaparral habitats) or is classed as non-vegetative, (i.e., rock). This percentage almost doubles when considering the land considered for treatment. This reflects the objectives and strategies behind the DFPZ land allocations, limited fuels and defensible geography. The strategic location of non-forested lands on ridgelines in combination of treating forestlands adds to the defensible characteristics needed for defensible fire protection zones.

Table 25: Stand Composition by Size Class within the Ingalls Project area

Size Class Code	Description of Size Classes	Ingalls Project Area		DFPZ/Area Thin (Proposed Action)	
		Acres	Percent	Acres	Percent
______	Non-forest	2,661	14.9%	1,181	28.8%
1, 2	Seedling, Sapling (0 to 6 inches DBH)	191	1.1%	13	0.3%
3	Pole (6 to 11 inches DBH)	2,037	11.4%	578	14.1%
4	Small Tree (11 to 24 inches DBH)	12,092	67.7%	2,264	55.3%
5, 6	Large Tree (> than 24 inches DBH)	878	4.9%	58	1.5%

Figure 5 shows the current diameter distributions for vegetation types that the project is considering activities in. The graph shows the typical J-shape curve that is represented by most untreated forest stands. A common attribute of J-shaped curves is that there are large numbers of younger, smaller diameter trees and as the stand grows these trees die. This process is evident lower numbers of trees as the diameter size increases.

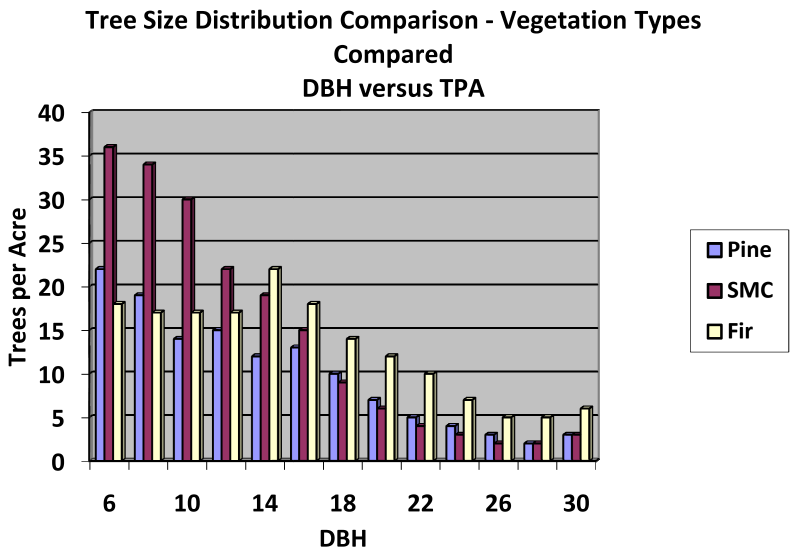

Figure 5: Current Diameter Distributions by Vegetation Type

Canopy Cover

Canopy cover is another component of the CWHR system. It is the amount of measured crown cover as a percent cast by trees greater than 5 inches diameter at breast height (Mayer and Laudenslayer 1988). As Table 26 indicates, the largest percentage of the vegetation is within the moderate crown canopy class, 40% to 59% closure. If we include the dense class, 60% and greater closure, this would include almost 50% of the entire acres we plan to treat within the DFPZ and Area Thin designations. The number of acres of higher canopy cover indicate that Ingalls stands show a propensity for growing shade-tolerant species, such as white fir. We can conclude from the number of acres within the higher canopy cover classes that the current probability for fire hazard and unpredictable fire behavior is likely higher then would be preferred or will become unacceptable within a short time period.

Table 26: Stand Composition by Canopy Cover within the Ingalls Project area

Canopy Cover Code	Canopy Cover	Ingalls Project Area		DFPZ/Area Thin	
		Acres	Percent	Acres	Percent
———	Non-forest	2,661	14.9%	969	23.5%
S	Sparse (10% - 24%)	1,698	9.5%	215	5.3%
P	Open (25% - 39%)	3,873	21.7%	917	22.4%
M	Moderate (40% - 59%)	7,506	42.0%	1,480	36.2%
D	Dense (> or = 60%)	2,120	11.9%	514	12.6%

Aspen Habitat

Of the aspen stands mapped and surveyed in 2004 on the Beckwourth Ranger District, the majority, 53 percent, were given a stand loss risk rating of highest or high, indicating that the stand was being hindered from overstory competition and/or not being replaced from below by regenerating sprouts. Stand assessments revealed that 63 percent of the aspen stands show aspen being competitively excluded by conifers, while an additional 19 percent are exhibiting less than optimal sprouting densities. This means that over 80% of the district's aspen habitats that were mapped and surveyed are in some risk status.

This risk assessment is supported by the fact that roughly 80 percent of the District's aspen stands were categorized as California Wildlife Habitat Relationship (CWHR) conifer cover types and not aspen cover types; including aspen stands within the Ingalls project area. Based on the CSE sampling within the Ingalls project, the averaged CWHR type for the aspens stands was a mixed conifer cover type, SMC2M.

The aspen/cottonwood stands of concern within the Ingalls Project shows these stands dominated by conifers in the overstory with canopy composition ratios of conifer to aspen as high as 10 to 0 or 8 to 2. Overstory conifers, 11" DBH and greater, within the project area are predominately white fir, ponderosa pine, Jeffrey pine or incense cedar.

Currently there is aspen regeneration occurring within these stands however, lodgepole pine has established itself and is beginning to compete with the aspen sprouts. This means over time the lodgepole pine will eventually shade out the aspen. The average conifer basal area calculated for the aspen stands in Ingalls is 79 square feet, or 85% of the total basal area with the majority of trees larger than 11" DBH.

Forest Vegetative Health

Insects and disease are important components of a normal healthy forested ecosystem, however could pose forest health problems if accurances are allowed to grow to large infestation or epidenmic levels. Due to fire exclusion, tree densities within the project area are much higher than a forest with a natural fire regime. The risk of insect and disease outbreaks are positively associated with higher densities (Fettig et. al. 2008; Powell 1999; Ferrell 1996). Therfore as stands become denser competition increases among trees for growing space (Reineke 1933), there is an increasing susceptibility to bark beetles and other forest insects and disease. Insects and disease left uncontained can potentially increase mortality, creating contributing to heavier fuel conditions over the project area. .

Pine forests support a variety of forest damaging insect species. These include both bark beetle (Dendroctonus sp.) and woood boring insects (Ips sp.). The most prevalent species within pine is the western pine beetle (Dendroctonus brevicomus). Other conifers, including white fir are hosts to other insect species. One speices of concern found in white fir is the fir engraver beetle. Forest damaging insects exist within the project area in endemic populations, but high tree densities place forest stands within the project area at high risk for epidemic beetle attacks.

In 2010, a Forest Entomologist/Pathologist with the Forest Service's Pacific Southwest Regional Office evaluated the project area (Cluck 2010). The Forest Entomologist noted several insects and diseases of concern within the Ingalls Project. The insects of most concern were the fir engraver beetle (*Scolytus ventralis*) and the flatheaded fir borer (*Melanophila drummondi*) which are attacking and killing white fir throughout the project area. Effects from these beetles are contributing to mortality within the project area. The specialist concluded that heavy stand densities combined with droughty weather conditions and stress from pathogenic diseases has contributed to an increase in insect infestations and eventually mortality in the project area.

Pathogenic diseases contributing to insect infestations include dwarf mistletoe (*spp. Arceuthobium abietinum, Archeuthobium campylopodum, Archeuthobium douglasii*) and annosus root disease (*sp. Hetrobasidion annosum*). Dwarf mistletoe infections are of greatest concern, because of the high infection levels within the project area. Most of the infections are in Jeffrey pine stands growing on shallow soils. These mistletoe infections are severe enough that there is an additional concern that the mistletoe infections are contributing to the increase of insect infestation from secondary attacks. Annosus root disease occurs in small pockets throughout the Ingalls project area, but currently does not have a major impact in the pine or mixed conifer vegetation types and has a moderate impact within fir stands. Throughout northern California, this pathogen is of concern, so the standard guidance from the USFS Regional office (R5) is to treat the disease after cutting activities with a borate compound registered by the State of California EPA for prevention of annosus root disease (see SOPs in appendix X).

White pine blister rust (*Cronartium ribicola)* is also present within the Ingalls project area. The disease occurs at very small levels in the project area, but is of high concern to the USFS Regional Specialists and Silviculturists. USDA-FS Region 5 has mandated protection for sugar pine to protect regional genetic resistance to this pathogen. Individual summaries of key insects and diseases pertinent to the Ingalls Project area are presented within the Ingalls Silviculturist Report.

Aspen Vegetative Health

Successful aspen sucker initiation relies on three key interacting components: hormonal stimulation, a proper growth environment, and protection of the resulting suckers. Hormonal stimulation causes suckers to grow from the roots of existing trees. This occurs when trees are stressed in some way through natural disturbances such as insect defoliation, disease, fire, climatic events, or when a parent tree dies. Aspen also need a proper growing environment to survive. This includes full sunlight to the forest floor and warm soil temperatures. Removing any conifers encroaching on the aspen stand may allow enough sunlight in to regenerate the stand and stimulate suckering. Mechanical harvesting of conifers can act as a sufficient disturbance mechanism by providing both minor hormonal stimulation, as well as create the proper growth environment required for successful aspen regeneration (Jones et al., 2005). Removal of competing conifers can also enhance any natural sucker production already occurring in declining clones (Shepperd et al, 2006). Protection from browsing is necessary for successful establishment of suckers and mitigation accomplished by constructing physical barriers or controlling animal movement. Any manipulation of aspen for successful regeneration must satisfy all three of these requirements. Techniques used to initiate aspen suckering and provide a favorable growth environment include removal of encroaching conifers through harvest and prescribed burning.

The effects of removing competing vegetation can result in dramatic changes in aspen regeneration and survival.

Since aspen is a fire-adapted species, prescribed fire potentially provides two of the three essential elements necessary for aspen regeneration. When used appropriately, prescribed fire is very effective in regenerating aspen. Killing overstory stems and injuring lateral roots provides the essential hormonal stimulation to initiate sucker production while removal of competing vegetation and blackening the soil surface (allowing it to be warmed by the sun) creates ideal growing conditions for suckers (Shepperd et al. 2006). Burning also releases nutrients that contribute to the growth of suckers. Although there is some application risk using prescribed fire, fire is probably what maintained many Sierra Nevada aspen/conifer forests in pre-settlement times. A combination of mechanical treatment and prescribed fire is usually the best course of action to regenerate aspen in mixed aspen-conifer stands. A combined treatment can provide a means of emulating natural fire regimes by providing maximum hormonal stimulation and optimal growth environments for aspen suckers as well as eliminating or reducing competing conifers (Shepperd, 2001).

Environmental Consequences

Alternative 2 – No Action

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Under the No Action Alternative, there would be no direct treatment of forest and other vegetative stands. There would be no implementation of management treatments to address the objectives or purpose and need of the Ingalls Project. This alternative allows stands to grow and develop according to normal successional processes and perpetuates the legacy of past management practices and fire suppression (Agee and Skinner 2005).

Measurement Indicator 1 – Stand Density

Existing stand conditions would change only through natural environmental processes. Stands would grow over time, influenced only by the environment in which they are developing. Current stocking levels for stands with moderate to dense crown canopy levels fall into a basal area range of 150 to 420 square feet. Open and sparse density stands average in the 50 to 160 square foot range. Without treatment, stocking densities will continue to rise over time resulting in a competitive increase between individual trees for moisture, nutrients and space. This leads to a loss of growth, diameter and height. Moderate and dense stands, show that over the thirty years of growth, basal areas will increase approximately 60 to 90 square feet. These denser stands are currently either overstocked or at or just below threshold (see Silviculture Specialist Report) for insect and disease risks. Stands with open and sparse crown canopy closures (<40%), have basal areas falling below the risk levels at which insect infestation may not be an immediate concern;

however the regenerative growth of younger trees is prevalent in these stands, which increases fire and insect risk based on tree spacing and clumpy stand conditions. .

For example, the average basal area of an EPN stand is 162 square feet, above the desired levels of 90 to 110 square feet. Because basal areas are at levels where serious health issues start to develop, there is an immediate concern about the health of pine stands. If left untreated for 30 years these pine stands are projected to grow to 276 square feet of basal area. This would place the average pine stand within the "critical" mortality range, risking potential epidemic insect infestations, thereby increasing the risk for ecological stand failure. If no treatment is implemented all stands show their basal areas and SDI levels increasing over the next 20 to 30 years. Therfore stands are growing larger and/or the numbers of stems are accumulating faster than natural mortality, increasing the potential of unhealthy stands which increases insect and fire hazard risks.

By breaking the "average" CWHR types into different density and size classes, differences in stand attributes between CWHR types can be shown.. First, the growth in the dense fir types (WFR) is not as dramatic because these stands have the presence of large diameter trees, which makes them densely overstoried. These conditions limit future regeneration and the effect diameter growth has on the increase in basal area. The basal area growth is smaller for the dense (D) fir versus the other CWHR types. The effect on diameter growth within the fir types is more evident using a QMD limited to measuring trees > 5". A second example can be seen with EPN4P (eastside pine, size 11-24", with crown closure from 20 to 40%), with an average basal area of 137. This basal area would not be of immediate concern because the basal area would fall in the "normal stocking" range of the pine stands. However, over the next 20 years the stand projection for basal area grows to 184 square feet with the quadratic mean diameter (QMD) falling 2" in diameter, indicating a rapid increase in smaller diameters that contribute to overstocking of the stand.

All stands except EPN4D show their basal areas and SDI levels increasing over the next 20 years. In EPN4D, basal area is stagnant and SDI has actually started to decline. This indicates that 4D eastside pine stands are over the 70% normality levels and are now in decline (mortality is larger than growth).

Measurement Indicator 2 – Stand Composition

The increase of basal area conditions would continue to favor tree species that are physiologically adept at growing under shaded conditions. These species would include white fir, red fir and incense cedar. Species such as ponderosa pine, Jeffrey pine and, to some extent, Douglas-fir would gradually be replaced by the shade-tolerant species. Over time, there would be a reduction of the overall percentage of pine within the overstocked stands. Pine stands would slowly convert to mixed conifer conditions, while mixed conifer slowly converts to white fir vegetation types.

Currently within the EPN stands, white fire and lodgepole pine are minor components of the stand, consisting of only 15% of the stand composition based on TPA (Figure 2). However, over time, both white fir and lodgepole pine will begin to invade the stand and the composition percentage of stems will increase. White fir is considered intolerant of fire, while lodgepole pine is more fire tolerant, but is considered a high-risk fire hazard species because of its ecological postion as a fire species and the species ability to contribute to undesirable fire behavior. Lodgepole pine is considered a fire speices because it ecologically uses fire to maintain its existence on the landscape. The species has the ability to use serotinous cones to regenerate after higher severity fires. Serotinous cones are specialized cones that release seed after fire. In the mixed conifer vegetation type, there is an observable transformation to a white fir type compared to the pine conversion to mixed conifer. Currently the stand type, based on TPA, has a stand composition that contains 50% white fir (Figure 3). Comparing this to the graph based on basal area we can see that white fir is regenerating into the mixed conifer, the percentage by TPA graph is greater than the basal area graph. This indicates younger white fir trees are invading into the SMC vegetation. This is also the case for incense cedar, even though it makes up a smaller part of the overall composition. Without any treatment (No Action Alternative) this invasion by white fir and incense cedar will continue, until the vegetation type converts to white fir or a disturbance by nature/man alters the ecological process.

The white fir vegetation types contain some remnant trees of ponderosa pine, Jeffrey pine and lodgepole pine (Figure 4). However, a lack of treatment activities will promote successional processes, and overtime these remnant trees species will die out of the stand until 100% of the composition is white or red fir. This will continue until either the stand ecologically collapses due to stand conditions and health or natural/man alter the ecological process.

Measurement Indicator 3 – Stand Structure

Stand structures, which are primarily single story now or those staging to multistory structures, will gradually convert to a multi-storied structure with a large number of understory trees. As the forest regenerates and younger shade-tolerant trees grow under the older mature overstory a crowding effect will develop. Without treatment, stand structures would be vulnerable to high severity wildfire, which potentially can be stand replacing, and would drastically alter the composition and structure of the forest vegetation within the project area. Figure 5 shows that on the average untreated stands in the Ingalls Project have started this development into a multi-storied status with large numbers of small diameter trees crowding the understory. However, ecologically over time the mature older trees will convert to the younger trees, returning the stand to a single story structure. Young trees will strongly influence average stand diameters keeping QMDs lower than treated stands. Stand growth rates would decline due to overly dense stands, while stand mortality would continue to increase. The result will be stands with overall stand and tree sizes much smaller than treated stands, with mortality levels eventually creating stand replacement conditions. Tree regeneration will continue to be shade-tolerant, fire prone species such as white fir.

Group Selection

There would be no direct effect on stand structures. However, an indirect effect is an immediate forgone opportunity of improving regeneration of fire resistant species and growing a healthier future forest.

Post Treatment Prescriptions

Under this alternative, no implementation of post activity treatments would occur. Small trees, shrubs, brush and other ground vegetation will continue to grow and accumulate on certain sites. Both ground and canopy fuel levels will increase over time as stands continue to grow, risking vegetation to stand replacing fire events. Stand basal area and crown density levels will increase to levels that potentially risk stands to insect infestation epidemics across wide landscapes.

Understory Vegetation

Since there would be no management activities, change in understory vegetation would be variable depending on the current stand conditions. Brush/shrubs in the short-term would continue to occupy their sites and either deter natural regeneration or slow the growth of currently established tree species. Sunlight environment preferred by brush and shrubs would become limiting over time as trees grow within forested stands. Tree canopies would shade sunlight out and brush/shrubs would slowly die-back over time. Regeneration of young fire resistant tree species would also decline as stands increase in tree density. Vegetation, which is shade intolerant, would be replaced by shade-tolerant species if seed source is available or the site currently contains and supports these species. . Eventually, even the regeneration of shade-tolerant species would decline when stand densities get to levels of full occupancy. Under Alternative 2, stand with denser canopies would have a consistent cover that would favor and be preferred by shade-tolerant species.

Direct and Indirect Effects of Improving Aspen Growing Conditions (Alternative 2)

Under Alternative 2, the treatment of aspen stands would not occur. Aspen stands would probably continue normal ecological progression, with no positive effects from management activity. However, there would most likely be negative effects from inactivity, including a decline in the stocking and regeneration levels of the aspen species and a loss of overall aspen health. Negative effects would likely occur over time because dense conifer forests would naturally replace aspen stands, raising the stand loss risk factor and increasing the perpetual loss risk of aspen clones from stand replacement fire in the future.

Measurement Indicator 1&2 – Aspen Stand Health and Condition

Tree health and vigor of individual aspen trees would probably continue to deteriorate. Old age, lack of quality sprouting conditions, and encroachment of conifers would be factors contributing to this deterioration. An ecological progression of conifers would take place; first shade intolerant then shade-tolerant conifer species would slowly invade the stand leading to a change of micro-site conditions that decrease aspen health. The current high stand loss rating of 4/5 (high category) would increase over time into the very high category. Insect and disease, which currently is not a serious problem, would be expected to increase over time as the stand ages and is not replaced by young healthy aspen trees. The combination of risk loss, increase in insect and disease and conifer encroachment would likely lead to higher mortality rates within all diameter classes. Large aspen would slowly die out and replacement through suckering and sprouting would not be sufficient in replacing the current stand.

Health and stand conditions that favor aspen regeneration through sprouting is likely to decline. The number of aspen sprouts per acre probably will decline as the stand ages and conifer invade the stand. As conifer species invade, canopy cover would increase, shading out the current aspen and future sprouts. Conifers most likely would become a higher percentage of the stand's composition and the ratio of conifers to aspen wouldchange from a low ratio to a high ratio. These stand conditions would decrease sprouting and regeneration, because sunlight would not reach the forest floor stimulating sprouting. This lack of regeneration would lessen the chances of aspen clones maintaining their current conditions. Conifer regeneration would continue and species composition should slowly convert from aspen to conifer. The number of aspen stems will likely continue to decline as conifer density increases over time. This ecological transformation is likely to threaten the existence of these aspen stands over the long-term.

Cumulative Effects of DFPZ, and Area Thin Treatments (Alternative 2)

Because there are no vegetative treatments proposed under this alternative, there would be no cumulative effect from treatment acitivites, but there would most likely be cumulative effects from no action. No action would perpetuate forest structures that are vulnerable to widespread change from fire, drought, insects and disease and climate change. Alternative 2 would not contribute to improving forest health and growth. Stand susceptibility to insect and disease infestations would potentially increase over time, especially during drought periods, leading to an increase of mortality levels. Other present and foreseeable activities such as fuelwood collection, Christmas tree cutting, and recreation would not have a positive cumulative effect on improving forest health; however, these activities have some potential for minor negative cumulative effects. These activities at current levels, if monitored, would have negligible cumulative effect on the project area. Fuelwood collection and Christmas tree cutting potentially have a negative cumulative effect on forest vegetation and regeneration if not monitored or the activities reach levels that may contribute to a higher cumulative effect. Fuelwood collection could potentially spread insect and disease to areas currently showing no infection. Fuelwood collection is also likely to have a cumulative effect on the number of snags present on the landscape, especially within reach of transportation system roads. Christmas tree cutting can also have a negative effect on areas in which regeneration is limited or an effort to regenerate lands is taking place, by removing established saplings. However, both would be limited to specific areas of the project where access by the public is frequent. Negative effects of climate change from the lack of management activites could potentially occur. Because there are no management activities, species that are suceptable to changes in climate (water availability, temperature) may become more prevelant on the landscape threating stand health and increasing fire hazard levels. Through management these negative effects could be mitigated, thus assisting the landscape during the climate's change.

Cumulative Effects of Improving Aspen Growing Conditions (Alternative 2)

There would be no positive contribution to cumulative effect on forest health or diversity from implemented activites. Alternative 2 would not contribute to improving aspen stand health or stand conditions. Application of no action most likely would create a negative cumulative effect on both growing and health conditions of aspen stands overtime. Aspen stands across the landscape are likely to decline over time, becoming a smaller percentage of the overall vegetation mosaic.

Alternative 1 – Proposed Action

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 1)

Under the Proposed Action Alternative (Alternative 1), existing stand conditions would change within DFPZ, Area Thin, and Aspen designated stands through harvest and fuel treatment activities. This alternative would treat designated lands using a "variable density thin" (VDT), group selection (GS), or an aspen prescription treatment. VDT would be the primary silvicultural treatment; however, implementation of GS prescriptions would happen in stand conditions where stand structure favors GS prescriptions. Implementation of aspen treatments would take place only in stands designated for aspen or cottonwood recovery. Removal of trees above 29.9" diameter would not be allowed under any of the prescriptions, unless the removal is for operability or under the Forest's hazard/ safety guidelines. In the VDT and GS prescriptions, preferential removal would be given to fire intolerant species, white fir and incense cedar, while ponderosa pine, Jeffrey pine and Douglas-fir would be left where feasible. This preferential treatment creates a stand condition that has a higher fire resistance.

Measurement Indicator 1 – Stand Density

The proposed prescriptions in Alternative 1 would alter both basal area densities (BA) and stand density indexes (SDI) for treated stands. In DFPZ designated areas EPN vegetation types were modeled to a square foot basal area level of 80 to 90 square feet for size classes in the 11" to 29.9" diameter group. The result is residual stand basal areas that range from 90 to 115 square feet of tree density; leaving an average basal area of 96 square feet for all EPN stands. Stands with higher CWHR densities, dense (D) and moderate (M), were treated much heavier than the lower density stands of open (P) and sparse (S). Because low density stands do not exceed the basal area objectives, implementation of VDT concepts will most likely be inconsistent across the landscape. In these low density stands, VDT concepts may be redefined to meet specific objectives needed under special circumstances. Example would be defining juniper species as legacies to meet special wildlife objectives. In the EPN stands, the modeling indicates that we can meet basal area density objectives of less than 120 square feet, a key preliminary point of insect/disease risk. Modeling also shows that on the average the VDT treatments would maintain forest health and insect risk for the next 20 to 30 years, based on the average basal area of 121 square feet in year 2041.

In the mixed conifer vegetation types, DFPZ modeled silviculture treatments lowered the basal area densities to the 120 to 130 square feet range in the size class group of 11" to 29.9". The resulting "total" basal area for the mixed conifer was 130 to 140 square feet for residual stands in the 3D, 3M, 4D, and 4M stands. These basal area levels met the stocking objectives as discussed in the Silviculutral Report for meeting forest health. The underlying reason for this result was the ability to meet crown canopy cover objectives of 40% in this vegetation type after treatment. As with the pine vegetation type, the addition and mix of smaller diameters allowed for more trees per acre being retained, thus leading to a higher canopy cover. The average residual stand in the mixed conifer would have 120 square feet of basal area after treatment. Modeling results indicate that VDT treatments to the square footage proposed would likely allow future stand conditions to maintain acceptable stand basal area levels for a period of 20-30 years.

In the DFPZ stands, fir vegetation types did not always meet the forest health basal area objectives. The intent was to model residual basal areas down to the 140 to 150 square feet of basal area in the size class diameter of 11" to 29.9". However, because of crown canopy objectives, the amount of basal area capable of being removed was restricted, for the 3D and 4M stands. To meet the minimum canopy objective in these two cases, modeled residual basal area had to be increased to 180 and 160 square feet respectively. In the 3M stands, the modeling at 150 square feet fell just below the canopy objective of 40%, but because of statistical variation, an assumption was made that this represented the defined objective. The resulting post-treatment basal areas of 202, 168, and 186 for the heavier stocked stands were above the residual basal area of 150 to 160 for normal forest health conditions following thinning. This result occurred because the current fir vegetation types (4M) has structures with larger diameter trees and does not have the tree per acre number within the smaller diameters. Thus, when we pattern the variable density across all diameters we end up taking some larger diameters needed to maintain canopy cover. Secondly, stands that currently are small in QMD (3D), have a large TPA number of much smaller diameters with very few larger trees. These small trees do not cast a crown as significant as the larger trees. However, these stand are so populated and dense with smaller trees that the VDT treatment cannot remove enough of the trees yet maintain crown canopy levels. Therefore, to meet canopy standards an increase in the residual basal area was needed to compensate for the low crown levels.

The modeled VDT prescriptions met SDI objectives for forest health with only a few exceptions. The exceptions were within the same WFR stands that could not meet basal area objectives. In the EPN stands, after treatment SDI levels were modeled to an average acceptable level of 156, with the denser stands carrying SDI levels of 165 to 185, just below the preferred thinning levels. Mixed conifer vegetation types show a similar result as the EPN vegetation types. Variable density thinning would lower levels to an appropriate SDI thinning level of 230 to 240. SDI levels under the WFR vegetation types demonstrates that the VDT silvicultural prescription would not get the SDI levels to the preferred post-treatment level of at least 280 for three of the specific vegetation types. However, under the DFPZ designation all three would get down to the "55% of normal" SDI competition level, but under the Area Thin designation SDI levels would remain marginally high for forest health expectations. Post-treatment outcomes indicate overall average SDI levels of 156, 211 and 267 for the three base vegetation types, EPN, SMC, and WFR. Therefore, on a landscape basis these SDI stocking values are well within the levels to maintain forest health and limit insect risk over the landscape, however individual stands may continue to see some problems with forest health, especially over the long-term without treatment sooner than the 20 – 30 year expected reentry cycle. The modeling results at the thirty-year mark indicate that the majority of VDT treatments would meet average requirements for forest health concerns.

Another objective under this alternative was to maintain a minimum level of crown canopy cover, therefore the VDT prescriptions were constrained by objectives for crown canopy cover. Crown canopy objectives were defined as average stand minimums; either a 30% crown canopy closure for eastside pine (EPN) vegetation types or a 40% crown canopy closure for the Sierra mixed conifer (SMC) and white fir (WFR) vegetation types that fell in DFPZ designated lands. Within Area Thin designated lands, crown canopy minimums were raised to 40% in the EPN types, and 50% in the SMC and WFR vegetation types. In modeling vegetation stands in this project area, crown canopy closure was considered a main objective that needed to be met; thus measures for forest health such as basal area, were considered secondary to crown canopy closure.

The Proposed Action Alternative was able to meet the crown canopy constraints in the vegetation types of concern within the project area. Stands of concern were the dense and moderate canopy covered vegetation types. In most instances, the open and sparse canopy covered stands were either at or below threshold, so treatment activity would be limited in these types. In the EPN stands, crown canopy closure averaged 33% after treatment. Dense and moderate pine stands were able to meet the basal area objectives and carry higher canopy cover than required. Open stands were either slightly higher or at the threshold of 30%, so treatment was limited due to the fact that basal area needs were met, and heavier treatments would lower crown threshold even more. Sparse stands were under crown canopy thresholds, and are projected to remain there through the next 20 to 30 years, even without any treatment activity.

To accommodate Area Thin designated acres a canopy cover objective of 40% cover was modeled in the EPN4D and 4M stands. Modeling indicates that both EPN stand types can achieve the 40% canopy threshold; however, basal area objectives would likely become a minor concern, since residual basal areas could only be lowered to 125 to 130 square feet. This indicates that forest health risk would be an issue in the short-term rather than the long-term. Results indicate that EPN stands classified as dense or moderate under CWHR would convert to either a moderate or open stand condition after treatment. Open and sparse designated stands would remain within these density classifications.

Sierra mixed conifer stands showed a similar result as the pine stands, with a couple of exceptions. First, the dense and moderate stands would likely not meet both basal area and canopy objectives. Any silvicultural treatment that significantly removed basal area would most likely just marginally meet threshold of 50%. Secondly, the open and sparse stands do not initially meet threshold (31%). In these stands, limited tree removal lowered the average crown density slightly to 28%. Only one SMC vegetation type under Area Thin clearly achieved the canopy constraints prior to any harvest treatment. This was SMC4D. However, after treatment to the 50% objective forest health risk would become a major concern within this vegetation type, because the residual basal area remaining, at 187 square feet, is well above the 130-140 desired. This stand type would also quickly grow to basal area levels above the desired maximums of approximately 200 square feet. Modeling indicates a square footage of 250 within the next thirty years. A second vegetation type of concern under SMC is SMC4M, which does not initially meet the 50% crown canopy threshold objective. CWHR results indicate that SMC, as well as WFR stands classified as dense under the CWHR classification, would convert to moderate stand condition after treatment. Moderate, Open and sparse designated stand would remain within these density classifications.

The fir vegetation types showed that only the 3M stand could meet both the basal area and canopy objectives. However, the other white fir types could only meet one of the two objectives, BA or CC but not both. The remaining white fir types would meet basal area objectives but prior to thinning do not meet the crown canopy threshold. The modeled average crown canopy cover under the fir vegetation type showed a crown cover of 37%. Only one white fir type was a concern under the Area Thin treatment, WFR4M. Results indicate that this type can achieve the 50% objective for the fir type, but forest health is expected to be critically compromised with a residual basal of 250 square feet. A residual basal area at this level is clearly above the desired maximum even after treatment. This means there would be a minimal gain to forest health from treatment. Even if the VDT prescription is applied, the treatment would be a short-lived and the need to return for future treatment would be high. Support of this assessment is a modeling result showing 313 square feet of basal area in the next 20-30 years.

Measurement Indicator 2 – Stand Composition

Stand composition by species changes under the Proposed Action Alternative. The change observed is a reduction in the percentage of white fir and an increase in percentage of fire resistant species (pine). The changes in percentages are a direct result of the preference removal of fire intolerant species, such as white fir, incense cedar and lodgepole pine. Comparing results from this alternative to Alternative 3 (Non-Commercial Funding Alternative), we should see a higher percentage of fire intolerant species removed. However, this would be dependent on the current species composition and stand structure of the stands prior to treatment.

Eastside pine showed a small loss of shade-tolerant species, because modeling targeted these species for removal to improve fire resilience of the stands. This means that stands designated as eastside pine (EPN) vegetation stayed classified EPN post-treatment. Post-treatment the EPN vegetation type still contained a percentage of fire intolerant species of white fir and lodgepole pine. These species remain because of the size diversity objective in the VDT treatment. In this prescription, the objective was to thin across the diameter classes, therefore to leave some smaller diameters the prescription was required to spatially leave some non-preferred species.

Mixed conifer had the most significant change. As the VDT prescription outlined white fir and incense cedar were preferred species for removal under the prescription. The targeting of these species for removal alters the vegetation type's average species composition. In Alternative 1, the modeled VDT treatment changed the percentage of white fir composition from 50% for initial stand to a 35% composition for the residual stand. Also shown is a decrease in the composition percentage of incense cedar from 24% to 14%. Compensating for the loss of these species, the vegetation type's composition of ponderosa pine, sugar pine and Douglas-fir all increased, from 23% to 40%, 2% to 5% and 1% to 6% respectively. Removal of fire intolerant species is controlled during the implementation phase of the silviculture prescription by attempting to remove as many stems of the fire intolerant species as feasible under the prescription.

For the SMC vegetation types, the CWHR classification of SMC would most likely remain SMC after treatment. However, there is potential in some instances where the type may change to an EPN vegetation designation. This would most likely occur in instances where the classification is marginally SMC under current conditions, and removal of fire intolerant species would alter the percentages so ponderosa and Jeffrey pine are the most prevalent species.

Stand species composition in white fir CWHR vegetation types most likely will not change from application of silvicultural treatments. WFR types will remain WFR post-treatment. Species composition under current WFR vegetation types contains a large percentage of white/red fir, 74%. Post treatment the average percentage for the white fir increases slightly however, ponderosa /Jeffrey pine percentages increase as well due to the removal of lodgepole pine, a species designated for preferred removal. Because of the large percentage of true fir species making up the current composition, converting these stands to SMC or EPN types would be difficult under a thinning prescription. Therefore, group selection treatments were considered within these ecological types for reducing forest health concerns and fire hazard/risk.

Measurement Indicator 3 – Stand Structure

VDT treatment would increase the quadratic mean diameter for the average vegetative types, however the overall residual QMDs for EPN, SMC and WFR will only increase slightly from current sizes. For example, the average quadratic mean diameter increases from 13.4 to 13.7 inches in the average EPN vegetation type. QMD also increases in SMC and WFR vegetation types, but the difference is slightly larger in these two types. The respective average change is from 9.9" to 11.2" in the SMC stands and 12.9" to 13.5" in the WFR vegetation type. The QMDs increase for all individual vegetation types except EPN4D, EPN4M and SMC2M. This indicates removal of more trees below than above the mean diameter in all vegetation types but three. In the EPN4D, 4M and SMC2M the opposite occurs, more trees above the mean removed, lowering the QMD in these stands. Within the EPN4D and 4M stands, this indicates stands were single storied with larger trees and fewer trees under the mean QMD. In order to meet the basal area objective, implemention of the VDT prescription required a larger number of trees removed in the 11" to 29.9" diameter group , thereby lowering the QMD. Since SMC2M represents the aspen vegetation type, there is an application of a conifer removal prescription and therefore the change in QMD does not reflect the VDT proposed in the other vegetation types. The treatment in SMC2M would be a complete removal of all conifers smaller than 30", resulting in a much lower QMD in the residual stand (please reference sections on aspen treatment contained in this document and the Silviculture Report).

Since the VDT prescription thins across diameters the CWHR size classifications would not be altered from application of this silviculture treatment. Change in CWHR size classification would only take place post treatment as stands grow over time. Stand QMDs will grow about 30% or 3 to 4 inches over the next 20 to 30 years. This would not be enough to alter the average CWHR size classes for EPN, SMC, of WFR, but potentially would change individual types from 3 to 4, or 4 to 5, depending on the current condition, the resulting residual stand and future growth on individual stands or vegetation types.

The small quadratic mean diameter changes are a result of the variable density thinning prescription, which removes trees across all diameters. By spreading removal over the diameter classes within the variable density thin prescription the stand maintains some multi-story function, and moderates the increase in average diameter size. **Error! Reference source not found.**, **Error! Reference source not found.**, and **Error! Reference source not found.** shows the effect of the variable density thinning harvest on the average EPN, SMC and WFR stands respectively. The stand will balance size classes maintaining some smaller size structures within the residual stand as compared to Alternative 3. The attempt is to have an equal number of stems per acre spread across all diameters. As the figures shows this will only partially happened in this entry cycle, but after several management entries, the achievement of the desired future diameter spread is accomplished. The current condition of the stand influences the resulting diameter distribution after treatment, so the number of entires to achieve the desired diameter spread will be dependent on the current stand diameter conditions. However, if we compared the residual diameter distribution of the "strict from below thin" (Alternative 3) to the variable density thin, there is a distinctive structure of trees in the lower diameters, which is not present under thinning from below. While the inclusion of these smaller diameter trees may not decrease the potential fire hazard to the maximum or optimum levels desired the prescription does maintain some vertical structure desired for future silvicultural options and wildlife.

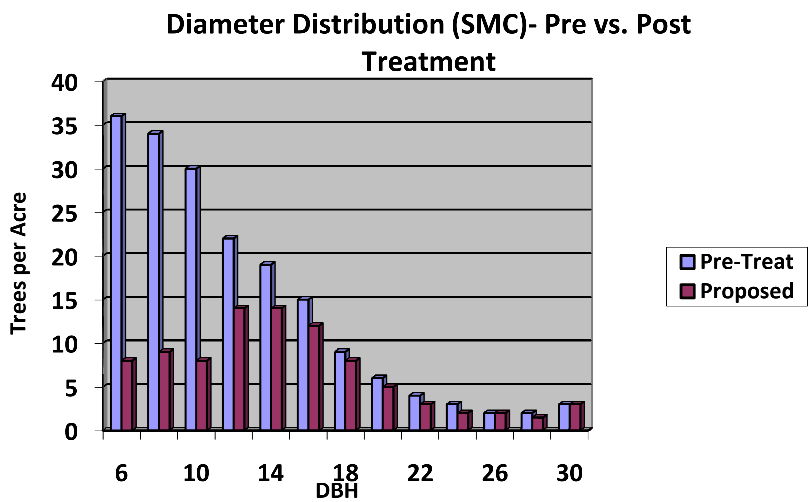

Figure 7: Average Residual Diameter Distribution of Mixed Conifer

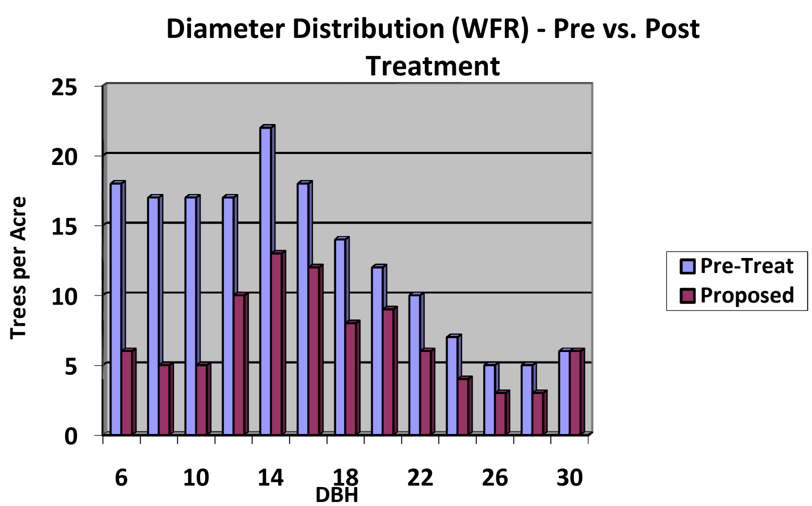

Figure 8: Average Residual Diameter Distribution of White Fir

Special Stand Conditions and Silvicultural Treatment

Certain vegetation types create a dilemma in the implementation of variable density thinning as defined within this document. The GTR 230 notes that VDT concepts pertain to sierra mixed conifer and do not completely fit with every stand type or appropriate for every stand (enter source). Some stands and stand types do not "classically" fit VDT concepts due to their current stand structure or stand condition. Therefore, under special circumstances prescriptions could potentially be altered to improve silvicultural outcomes. .

A modification of VDT would enhance and promote objectives under these special situations. Example, juniper tree species are valuable species for wildlife habitat and diversity, hence it is essential to manage this species under special rules. This species primarily occurs in open and sparse vegetative conditions, therefore in these stands, variable density thinning is not a perfect fit, but an adjustment in the VDT prescription would improve the stand's conditions and structure and move it to toward the desired future condition. This adjusted prescription would be limited and not change current stand conditions significantly. Crown canopy, basal area or trees per acre levels would not be altered an adequate amount to change CWHR habitat classification.

Group Selection (GS)

Group selection is an uneven-aged regeneration method and is an intermediate treatment to address short-term objectives of stands.One specific objective of this prescriptive treatment restoratively treats specific stands where variable density thinning practices have limited effectiveness because regeneration and young trees are a missing component of the stand. Generally, these stands would be single storied, larger diameter stands where the trees are spaced on an equally spaced grid. The intent of the prescription is to break-up the homogeneity of these stands, initiate the ability of stands to become structurally multistoried, multi-aged and vertically structured over time and improve forest health. Under group selection, forest health is likely to be improved by selecting groups or trees with the highest risk from insect and disease.

Group selection would alter total stand structure by creating small openings of less than 2 acres within designated stands. Basal area would be non-existent in the openings, except when residual trees over 30" remain or when selected residuals are retained to provide a seed source for future regeneration. The resulting residual stand structure and conditions would vary depending on the needs of the group and current stand conditions. Residual structures within the openings could potentially be any structural pattern from a few seedling/saplings to a pattern that has a few scattered trees of various diameters, generally not exceeding 10 trees per acre. Basal area growth would occur over the ecological rotation of the stand; for most vegetation types in this project area this would be from 70 to 150 years.

A large reduction in canopy cover and stand density occurs in order to create a favorable environment for promoting and establishing shade-intolerant conifer species such as ponderosa pine. Group selection would convert small areas of large CWHR size class structures to CWHR size class 1 structure with a few large remnant trees however, these openings would not alter the overall stand CWHR. Residual stand over-story structure in the openings would be comprised of less than 10 trees per acre, in which the size will vary from 11" to over 30 inches in diameter. Groups would have an open stand structure with sparse canopies, generally less than 10% cover. Diameter distributions within the openings would be representative of a one to two stage stand depending on the number of larger over-story trees retained.

Regeneration of approximately 170 to 240 trees per acre within the group openings would establish a desirable forest stand in the future. The ability of group selection to promote establishment and development of shade-intolerant conifer regeneration is largely dependent on the size of opening (York et al. 2004). Establishment and development of shrubs and other vegetation is expected. However, group selection could be used as a silvicultural technique in reducing and controlling competing brush species for regeneration (McDonald 1999). They observed that within smaller units, "normally aggressive shrub species were never really competitive"; however, they also noted that shade-intolerant species were less successful in their growth development. Shrubs and brush are recognized as part of the vegetation and stand component and removal treatments would take place only if brush is considered a hindrance to regeneration, or treatment is needed to lower fire risk, and the stand has been designated for post-treament.

Post Treatment Prescriptions

Direct and indirect effects of these prescriptions would be the same. However, the type of treatment as a post-treatment to thinning may differ from unit to unit. Several fuel treatment prescriptions will be implemented within this alternative. Hand thinning would take place primarily in Riparian Habitat Conservation Areas, on stands where slope exceeds operational SOPs, and within specified stands where tree densities do not warrant mechanical operations. The treatment would affect structural diversity because most trees under 8" would be removed. The amount of structural change would depend on the initial stand structure and the number of smaller trees within the initial stand. Crown canopies would only have a minimal change because most crown cover is cast by the larger trees structures within the stand. Effects from hand thinning on stand change is expected to be equal or less than the strict thinning from below (Alternative 3) because the 8" limit is either equal or lower than the UDL proposed under Alternative 3. Change of CWHR classification would be nominal, but we expect QMD to increase for the stand, and basal area and TPA to decline. Stands that are marginally between size and density classifications may be altered. Stand size may jump from 3 to 4, in some instances density may fall from D to M or M to P. It is anticipated that vegetation classification of the CWHR would not change thus, EPN, SMC or WFR classifications would remain the same.

Hand thinning, under most circumstances, will improve forest health conditions by reducing the small tree structure, lowering basal area, and making nutrient and water available to the larger tree component. However, if the stand only contains a small component of small trees, hand thinning may not improve forest health if the upper structure still has a high stand density. Under these conditions, removing the lower structure would marginally improve forest health and insect risk, but leave density levels and fire risk higher than preferred levels. Thus, hand thinning may only have a minimal effect on forest health, and probably would require future silvicultural activity entries sooner than units treated with mechanical thinning.

Mechanical fuel treatments such as grapple piling and mastication may or may not affect structural conditions. In certain situations, pre-commercial thinning by either hand thinning or mechanically of trees less than 12 inches may occur. The result would be the same as for hand thinning except additional trees smaller than 12 inches may remain as residuals. Grapple piling would primarily proceed in stands where large woody debris, brush and small trees are the objective for removal. Grapple piling would remove a portion of the woody debris, shrubs, brush and unwanted trees under 12 inches. Treated material would be piled, and then burned, after a period of curing. Hand pile burning can scorch nearby residual trees and has the potential of inducing additional thinning through mortality loss. By keeping piles small, and burning under prescribed conditions, the mortality results of pile burning should be negligible.

Mastication treatments would occur primarily in areas that are open to montane chaparral and in conifer stands where mechanical treatment (grapple piling) or underburning is not viable. This decision is made based on current fuels levels or fuel levels left by the mastication treatment. Mastication treatments alter the vertical arrangement of brush fuels by converting live aerial fuels to dead surface fuels. Conifer saplings and larger trees would be avoided during treatment to encourage establishment of forest vegetation cover. Mastication treatment would contribute to the duff and litter layer, which may inhibit vegetation growth as well as forest regeneration. Over time, the duff and litter layer will decompose, eventually allowing growth of immature brush species and tree regeneration.

Underburn by prescribed fire would reduce fuel loading by consuming down woody debris, litter and duff. The treatment would likely scorch smaller lower canopy trees which could result in mortality of individual or isolated pockets of residual trees; however, this effect is expected to be minor on the stand level. Underburning would have a minimal effect on forest vegetation and structure. The treatment would create a mosaic of ground conditions, leaving bare mineral soils in some areas and vegetation intact in others. In areas where bare mineral soil has been exposed, sprouting of brush and tree regeneration would re-establish themselves in a short time period. Underburn activities will avoid stands where ground fuel levels risk heavy scorch on fire-intolerant species, unless another post treatment activity is used prior to the underburn.

Understory Vegetation and Regeneration

The clump and gap ideology of variable density thinning would create openings and lower tree densities, which would encourage regeneration of shade-intolerant species such as ponderosa pine. By lowering basal area and crown canopy cover, sunlight would be available to the forest floor encouraging shade-intolerant species, and slowing shade-tolerant species from regenerating.

VDT will also maintain small diameter trees that would not be present under Alternative 3. Understory vegetation would potentially increase immediately after tree removal in stands treated under either variable density thinning or group selection. With the addition of more sunlight, brush, shrubs and grasses would increase within lower density areas of residual stands. Post-activity DFPZ fuel treatments would initially decrease the amount of brush and shrubs; however, over time they will return from sprouting and regeneration. Grapple piling either as a post-treatment or as the only treatment would decrease ground vegetation. Future establishment would depend on the quality of the treatment, the retained vegetation, and future seed source of the vegetation. Mastication activities would also decrease the ground vegetation, but re-establishment of the vegetation would probably occur quickly through sprouting of existing remnants.

Direct and Indirect Effects of Improving Aspen Growing Conditions (Alternative 1)

There are numerous aspen vegetation stands found within the Ingalls project area. The removal of conifers would create suitable habitat for the aspen species to increase in number, diameter size, and productivity. A report by Jones et al. (2005) indicates that conifer removal was effective in the regeneration of aspen stands. Four years after silvicultural treatment, an increase in aspen density was shown across all age classes as compared to stands not treated. It is expected that short-term negative impacts may occur but natural ecological recovery should reinvigorate the stand's growth; therefore these impacts should be short-lived with favorable long-term results to aspen vegetation and conditions.

Measurement Indicator 1&2 – Aspen Stand Health and Conditions

Tree health and vigor of individual aspen trees would increase with stand treatment. The stand loss risk rating, which is currently high, lowers after treatment. Aspen risk loss would remain stable for a period then over time start to increase again with coniferous evasion. Insect and disease levels, which are not considered a current problem, would be maintained at the same level. Aspen improvement activities under this alternative would be preventative against future infestations. Mortality levels in the all diameter classes should be improved. Larger older trees should become more vigorous, because stocking of conifers would be decreased, increasing nutrient/water availability and growing space for these larger aspen. Sprouting would be encouraged consequently increasing the number of young aspen. Newer, younger trees with better growth and lower mortality rates would be prevalent in the improved stand. Conifer species competition would be reduced , thus the aspens would be "free" to grow. Both older and younger trees would see an increase in growth vitality over time due to an increase in sunlight availability. Older tree health would improve, but ecologically this health would be transmitted to younger trees instead of invading conifer species.

Under Alternative 1, conifer species would be removed creating canopy cover conditions that promote and support aspen sprouting. The removal of conifer species would open the stand canopy to sunlight, a factor essential to the regeneration of quaking aspen. This sunlight would create microclimatic conditions such as a rise in soil temperatures, which leads to increase in aspen clones sprouting. Sheppard et al (2006) showed that this removal of conifer competition and increasing the composition percentage of established aspen within a stand, lead to an increase of sprouts within five years after the harvest activity. This author also showed that light soil disturbance from silvicultural activity also promotes additional sprouting, increasing regeneration, and the chances of aspen clones maintaining or improving their current stand conditions.

Cumulative Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 1)

Forest health and growth cumulative effects analysis considered past, present, and foreseeable projects within the Ingalls project area boundary. Forest activities over the past 20 years, which would affect forest health and growth, have been limited both within and immediately outside of the project boundary. Several vegetation projects are currently being implemented nearby the Ingalls project boundaries. Two specifically are the Grizz and Freeman EA projects. Both projects include both DFPZ and forest health guided objectives. Foreseeable future projects within the Ingalls project area that affect vegetation include future DFPZ treatments, recreation, fuelwood cutting (firewood), and Christmas tree cutting. These activities are expected to have negligible effects on forest densities, species composition and stand structures and therefore forest health. Another consideration is the cumulative effect of climate change on forest landscapes over time.

Past forest management activities have been limited in this project area; however natural activities such as wildfire have taken place. These fires have remained small and have been suppressed when they have occurred. In relation to forest health, these fires have had both positive and negative contribution to the health of the forest. These fires have replaced primarily overstocked stands that would have contributed to insect infestations but suppression has limited the effectiveness of these fires on a landscape scale. Because of this, the cumulative effects from vegetation treatments would improve the health of the stands and vegetation within the project area, and tree removal for forest health and growth would have short-lived and minor cumulative effects over the landscape.

Of projects previously mentioned, DFPZ treatments potentially have the greatest impact on cumulative effect. However, given that this type of activity would be follow-up to management activities proposed, the timeframe of those treatments is probably 10-15 years into the future. Based on this timeframe, the only affect future DFPZ treatments could potentially have in combination with alternatives proposed would be potential negative cumulative effects on regeneration establishment in stands treated. However based on previous DFPZ activities and research studies this seems to be insignificant to forest development, structures, and forest health/growth. None of the other activities would add significantly to the cumulative effect on forest structure, composition or health/growth.

Numerous forest activities have been identified adjacent to the project area. These activities would have no or only a minor effect the forest health and growth within this project area, and therefore have a limited cumulative effect on forest health and growth. Treatment of vegetative stands adjacent to the project would reduce risk of epidemic spread of insect populations into this project area however, because the number of acres being treated next to this area and treatment of nearby private ownership is minor the directly cumulate effect to the Forest Service landbase would be small.

Personal and commercial use fuelwood programs are ongoing, as is the DFPZ treatment program on the district. Fuelwood cutters remove approximately 1,000 to 1,500 cords of firewood yearly, primarily in the form of snags and large woody debris. This activity is limited to within 100 feet of the forest's road system. The firewood cutting program would have a limited cumulative effect on forest health. Trees removed may assist in controlling insect populations by removing potentially infected trees, but also have the potential to spread insect and disease from isolated areas. However, most trees harvested would be beyond their infectious stage, thus this activity would only have a minor positive or negative cumulative effect. Removal of fuelwood would not have a cumulative effect on overall stand conditions to effectively manage forest health or growth. Christmas tree cutting activities could potentially have a negative cumulative effect on stand regeneration and management for fire resistant species, especially in areas that are easily accessed during the seasonal permit. However, this probably is not a major concern since white fir and red fir are the species of preference over pine when selecting Christmas tree stock. Therefore this activity would have no or limited overall cumulative effect on forest health/growth. Recreational activities would have no cumulative effect on forest health or stand growth.

The treatment activities proprosed now and in the future potentially have the cumulative effect of mitigating effects from climate changes over time. By altering and favoring fire resistant species in future stands, changes from a potentially warming climate will mitigate fire hazards, and increase the survivability of species under warming and droughty conditions.

Cumulative Effects of Improving Aspen Growing Conditions (Alternative 1)

Measurement Indicators 1&2 – Aspen Health and Stocking

The effects of past activities are built into this analysis, since these activities were largely responsible for the current landscape. Management and natural activities have cumulatively affected aspen communities and include; timber harvest, wildfire, fire suppression, prescribed fire, road construction, domestic grazing and activities that have changed water flow patterns. Previous historical fire suppression, wildfire, and other activities have had a potential negative cumulative effect on aspen communities. The absence of natural fire regimes has contributed to the decline in aspen ecosystems across landscapes. Wildfire at severe levels risks damage to aspen clones and replacement by other habitats, such as brush fields, which develop naturally adjacent to these aspen ecosystems. Overtime brush habitats will grow and increase the future fire risk from severe wildfire. By treating aspen stands, removing conifer and promoting aspen a buffer is against potential wildfire in the future. Under Alternative 1 the treatment of aspen stands and removal of conifer would have a positive cumulative effect on the establishment, stocking and growth of aspen within the stands treated.

Other activities such as watershed restoration projects, fuelwood collection, and recreation do currently occur directly and indirectly within aspen vegetation types. Watershed restoration projects have taken place in the past and will occur in the future within the Ingalls project area. These projects can affect aspen habitats; however, these projects are designed to help restore the natural hydrological regime and should have a positive cumulative effect on aspen in these projects. Fuelwood collection and recreation would have marginal to no effect on the aspen habitats being treated under this alternative.

Cumulative Effects of Forest Access and Transportation Management

The small amount of transportation management activities would have negligible impact on the overall forest health and growth of the forest within the Ingalls Project. Road obliteration would not alter any vegetation, but would encourage reforestation of non-forested acres. Over time, vegetation would encroach and establish within the old road profiles. Temporary road construction would remove all forest vegetation within the road profile; however obliteration of these temporarily constructed roads would mitigate the vegetative effects. In addition, the road activity would be less than 0.1% of the total acres being treated through other activities, a very low impact on the forest vegetation overall.

Alternative 3 – Non-Commercial Funding

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 3)

Alternative 3 (Non-Commercial Funding Action) would treat only acres designated as DFPZ. Treaments would be implemented under a single objective of reducing fire risk to a predetermined level. Units would be treated by mechanical thinning using a “strict thin from below” prescription to an upper diameter limit (UDL) that would meet the fire and fuel objectives. These UDLs would remove understory trees through a strict application of an upper DBH limit without other silvicultural considerations. Trees removal would occur without consideration to commercial status, species preference, desired silvicultural stocking or current insect/disease infection. This means that there would be limited preference for conifer tree removal or harvest based on species, tree vigor or tree health. Tree diameter would be the primary discretionary selection point.

The upper diameter limits to meet the fire and fuel objectives would range from 8” to 16” depending on the CWHR vegetation type. In eastside pine (EPN), UDLs would be either 8” or 10”; in mixed conifer (SMC) they would vary from 8” to 16” and in white fir (WFR) the range would be 8” to 12” respectively.

Measurement Indicator 1 – Stand Density

Treatment under this alternative would remove understory and depending on the UDL some mid-storied trees, leaving only an over-story of residual trees. Stocking, tree size, crown canopy and other silvicultural conditions of each residual stand will vary depending on the initial vegetation type.

Since basal area density is not a prescriptive objective under this alternative, the resulting basal area density is an indirect effect of the silvicultural treatment for fire hazard. The basal area stocking levels within stands treated would be lowered due to the removal of trees. In both eastside pine and mixed conifer the resulting basal area densities for the open and sparse crowned stands fall within acceptable forest health levels for the long-term. Eastside pine basal area levels would be at levels below 110 square feet per acre, and would be acceptable 20 to 30 years out in time. The “thin from below” treatment under this alternative would not meet the desired forest health objectives for basal area under moderate or dense EPN stands. Basal area levels above 130 would continue applying stress to EPN stands leaving them at higher risk for insect infestation. This was extreme under the dense stands with basal area levels in the 190s for the both the 3M and 3D vegetation types. These basal area levels would be at values where insect and disease becomes a serious problem and tree mortality potentially is quite heavy. Basal area remains at levels where additional thinning should occur.

Modeling of the mixed conifer vegetation types showed all stand types meet the basal area objectives and forest health needs of Alternative 1, except for SMC4D, which would be treated to 190 square feet. Therefore, SMC4D stands would remain at risk to insect and disease. SMC vegetation types were able to achieve the forest health objective due to a higher UDL than those of the EPN types. In the white fir types, only one vegetation type was able to meet the basal area objective, 160 square feet for this type. The other WFR types are above the forest health threshold after treatment and WFR3D stands are very high and close to levels were additional treatment would be needed sooner than later to alleviate forest health risks.

Under Alternative 3 the majority of pine, Sierra mixed conifer and true fir vegetation types would meet the preferred stocking levels after thinning under a SDI evaluation. Post-treatment data indicates that three pine, one mixed conifer and two fir vegetation types do not meet the preferred SDI thinning levels. The six vegetation types fall in an initial canopy cover level of dense or moderate. The lack of adequate thinning and the heavy crown cover indicates these stands had high initial SDI levels. This is the case with all stands having an initial SDI level falling at or above the “health issue” range.

The average EPN type under the “strict-thin from below” prescription did not meet the preferred thinning SDI level of 210, achieving only a 218 SDI level. This indicates that the three vegetation types, EPN3D, EPN4D and EPN4M, have a big influence on the whether the overall pine landscape meets forest health objectives. With post-treatment SDI levels of 299, 326 and 264 these three vegetation types would need additional treatment in the short-term to avoid potential health risks from insect and disease. The average SDI density level falls below concerns in some stands, but not thinning areas to a desired thinning level would shorten the reentry period needed to maintain landscape forest health in the future. In the SMC classification, only one vegetation type shows some indication of potential forest health risks in the near future. SMC4D data shows a residual SDI level of 272, which is below the “health issue” range, but not thinned to the preferred SDI level that would protect the stand through the next 20 to 30 years. Two WFR vegetation types show the potential health risk after treatment. WFR4M is similar to SMC4D, in that UDL treatment was not to a SDI level that would carry potential forest health risks far enough into the future. WFR3D, with an initial SDI level of 754 is in the critical mortality range. This result means that stands in this vegetation type are at risk of complete ecological collapse, with the potential of becoming small sized/low density stands. The “strict thin from below” treatment left a residual SDI of 521, leaving the SDI in the health issue range, and only providing a minimal improvement in forest health protection.

Canopy cover was not considered a constraining objective for the “strict thin from below” prescription. Since the “strict thin from below” prescription removes smaller and generally lower levels of basal area than the VDT prescription. In Alternative 1, all stand types in the eastside pine, and white fir vegetation types met crown cover threshold goals, when accomplishment was feasible. However, because the prescription calls for a “strict” removal of understory, open and sparse stands, that generally do not meet crown cover thresholds, have crown canopies lowered to levels slightly lower than those in Alternative 1. Example, the residual crown cover percentage for EPN3P under this alternative is 27%, a little lower than Alternative 1’s 29%. The same holds for white fir, WFR3P data shows residual crowns of 21% versus 24%.

Canopy data results for the mixed conifer were opposite those of EPN and WFR vegetation types. The resulting average crown canopy percentage for the SMC vegetation type was 28%, compared to 40% and 44% for EPN and WFR respectively. To achieve the fire risk objective of the prescription, crown levels were lowered below the threshold goals. All but one SMC stand type fell below the canopy thresholds. The only vegetation type to meet our goal was SMC4D with a residual canopy cover percentage of 47%. This indicates that the mixed conifer stands contained many smaller trees that contributed to the crown canopy and needed to be removed to improve fire behavior. Mixed conifer stands at or below threshold prior to treatment showed the same result as EPN and WFR stands. Canopy percentages were lowered to levels slightly below those shown in Alternative 1, showing the inflexibility of the “strict” UDL removal.

Measurement Indicator 2 – Stand Composition

The “strict-thin from below” (Alternative 3) silvicultural treatment may only minimally alter the species composition of the stands. This alternative’s prescription does not have a direct removal preference as to which species warrant removal over others. Instead, diameter size is the method of preference, and therefore selection of intolerant fire species for removal depends on how species fall into diameter classes. Species that are shade-tolerant and generally considered fire risk species (white fir) will not have a higher priority of removal over other species. Shade-tolerant species would have a higher probability of remaining within the stand composition, because shade-tolerant species may be present in diameters that are not allocated under the UDL. If these species are larger than the upper diameter limit (UDL) then they would not be selected for removal, which could potentially happen under Alternative 1. Overtime this will have the effect of encouraging continued growth and regeneration of these shade-tolerant species. Removal of “less desirable” species would occur if they were present within the diameters being harvested. The highest “UDL” for any particular vegetation type is 16”, thus only less desirable trees below 16” would be removed from that specific stand. The result is that the time effectiveness of the fire hazard treatment would be shortened due to remnants present to contribute to regeneration of shade-tolerant species. This is due to the removal requirement of the strict UDL limit, instead of being flexible under the VDT prescription.

The UDL thinning was not a hindrance to removing shade-tolerant, fire prone species in the EPN or SMC vegetation types. The lack of a species preference objective is not a factor in the application of this prescription. In both cases white fir, incense cedar and lodgepole pine composition within these vegetation types declined, while ponderosa pine, sugar pine and Douglas-fir increased. For example, white fir and incense cedar percentages declined from 50% to 35%, and 24% to 13%, while ponderosa pine increased from 23% to 41%. In addition, there are modeled increases in sugar pine and Douglas-fir, which currently occur in low percentages. These slight increases combined with the opening of stand canopies from thinning could potentially encourage future regeneration of these species. An opposite result emerges in the WFR vegetation type, the percentage of white fir increases after treatment, going from 74% to 91% of the vegetation type’s composition. This happens at the cost to ponderosa pine, Jeffrey pine and lodgepole pine, which become smaller percentages of the overall composition. In this case, the shade-intolerant species must have found areas to regenerate and by treating using the UDL prescription these younger trees with smaller diameters were removed.

Measurement Indicator 3 – Stand Structure

The “strict thinning from below” will alter the average QMD of the stands being treated. Overall stand QMD size will be increased. The proposed silvicultural treatment will increase the quadratic mean diameter for all vegetative types. For example the average EPN vegetation type QMD increases from 13.4 to 18.6 inches, the average SMC QMD increases from 9.9 to 20.3, while the average WFR QMD increases from 12.9 to 19.4. This increase significantly shows the stands becoming more single-storied than prior to harvest. This phenomenon is because only lower and mid-storied trees are being removed under this alternative’s prescription. The difference between the Proposed Action and Non-Commercial Funding Alternatives is that residual trees will be present across the lower diameters with the Proposed Action because the VDT prescription does not have a firm UDL at which tree removal must occur.

Group Selection

Under this alternative, group selection would not be implemented; therefore no effects would occur from this silvicultural activity.

Post Treatment Prescriptions

Post fuel treatment prescriptions would remain the same as Alternative 1; however, post-treatments would only be implemented on DFPZ designated lands. The direct and indirect effects of these prescriptions would be the same as Alternative 1 (Proposed Action); however, the difference in the applied silvicultural prescription may alter the post-fuel treatment employed from unit to unit.

Understory Vegetation

Like the No Action Alternative, canopies would tend to have a consistent cover that would limit the amount and growth of brush/shrubs. The brush component of the stand would decline during treatment, but gradually increase after treatment. Under this alternative growth and regeneration would be lower than Alternative 1 because of the overstory canopies left by the silvicultural prescription. Brush would become exposed to additional sunlight and nutrients due to the removal of small diameter trees, but not to the extent of Alternative 1 because a higher percentage of canopy cover would remain in most vegetation types. Exposure to sunlight and additional nutrients would increase growth and presence of brush species. However, since the removal of basal area varies depending on the vegetation type, some types would show less brush growth than other types. Example, under the dense and moderate canopy stands basal area after treatment would be higher than under Alternative 1, therefore the residual canopies, and lower levels of sunlight and available nutrients would minimize growth of the brush. In the higher density stands, basal area will remain high even after treatment, thus the probability of a large quantity of ground vegetation growth is limited due to the canopy shading effect. Ground vegetation that does sprout will die-back more quickly under this prescription. This is due to the number of residual trees remaining and quick restoration of basal area to the stand after treatment.

Brush would be most prevalent in the lower density stands (open and sparse) because the strict thin from below UDL prescription would actually remove more basal area than the Proposed Action Alternative. This would open these lower density stands even further adding to the potential of more brush. The amounts of additional brush would depend on the site and soil conditions of these lower density stands.

Regeneration intensity would be lower and seedlings that establish would have slower growth rates under this alternative compared to Alternative 1. Shade-tolerant species will be favored due to the number of mid to large diameter trees maintained in the residual stand structures. Since residual basal area is higher than under normal thinning practices, white fir and incense cedar will be the favored species in regeneration. Open density (P) stands will have some pine regeneration, which would be preferred, but stand density growth will lower the pine regeneration potential over time. Because stand regeneration will favor shade-tolerant species (white fir, incense cedar), future activities would need to be more frequent, making reentry sooner in an effort to maintain the fire/fuel objectives.

Direct and Indirect Effects of Improving Aspen Growing Conditions (Alternative 3)

Like the No Action (Alternative 2), the Non-Commercial Funding Action (Alternative 3) would not have any treatments within aspen stands. Aspen stands designated for treatment under Alternative 1 would not occur therefore, the direct and indirect effects would be the same as Alternative 2.

Measurement Indicators 1&2 – Aspen Stand Health and Conditions

Effects would be the same as Alternative 2.

Cumulative Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 3)

Alternative 3 is likely to maintain higher canopy levels in general, leaving more dense/medium canopies on the landscape. Measurement indicators in Alternative 3will also be slightly different compared to the other alteratives due to difference in prescriptions implemented. The cumulative effect of these measurement indicators is that reentry may need to be more frequent to address changes in stand conditions contributing to quicker return of insect infestation risks from the prescriptions implemented. Other cumulative effects of this alternative would be the same as Alternative 1.

Cumulative Effects of Improving Aspen Growing Conditions (Alternative 3)

Cumulative effects would be the same as Alternative 2.

Economics

Introduction

Demographic and economic data was analyzed to determine the socioeconomic impacts the Ingalls Project has on Plumas, Lassen, and Sierra counties, and their associated communities. Data was analyzed based on local economic information from these counties.

The wood products industry is a major employer and revenue generator in these counties. The majority of the contractors who bid and work on projects on the Plumas National Forest reside in Plumas, Lassen and Sierra counties. The communities in these counties are dependant on the forest products industry for jobs and revenues. These communities are isolated from urban job markets, resulting in their reliance on natural-resource based industries. Because of their rural location, these counties are also more dependent on natural resources than other counties in California.

The Herger-Feinstein Quincy Library Group Forest Recovery Act (HFQLG FRA) 1999, Appendix S, and Appendix T describe the direct, indirect, and cumulative socioeconomic impacts of implementing the HFQLG Pilot Project. Therefore, this economic analysis will not revisit the information presented in the HFQLG FRA, but will focus only on those revenues and treatment costs associated with implementing thinning and fuels reduction treatments within the Ingalls Project area.

Affected Environment/Economic Consequences

Affected Environment

Timber Yield Tax

Yield taxes are based on values established by the state for various timber products, as determined by analysis of market transactions in a given area twice each year. On Forest Service land the tax is paid by timber operators or purchasers, based on the amount of timber harvested in a given year. Currently, the 2011 tax rate is 2.9 percent of the State prescribed value of the harvested product. Generally, 80 percent of the yield tax would be returned to the county from where it was collected

Employment

Employment opportunities can have direct, indirect, or induced effects on the local economy. Direct effects are associated with the primary producer. For example, the manufacturing of lumber or other wood products would have a direct effect on employment opportunities for individuals within Plumas, Lassen and Sierra Counties. Indirect effects account for employment in service industries that serve the lumber or other wood products manufacturer. These industries may include logging, trucking, and fuel suppliers. Induced effects are driven by wages. Wages paid to workers by the primary and service industries are circulated through the local economy for food, housing, transportation, and other living expenses. The sum of direct, indirect, and induced effects is the total economic impact in terms of jobs, which typically range from 10 to 15 jobs per million board feet of timber harvested.

Receipt Act Payment

Receipt Act payments are distributed pursuant to the National Forest Management Act (Public Law 94-588). Under this law, 25 percent of the National Forest revenues are allocated to the state in which the forest is situated. For the Ingalls Project, the Plumas National Forest is expected to contribute 25 percent of the advertised rate in Receipt Act payments to Plumas County. These payments go back to the county where Receipt Act funds are divided between public schools and public roads. However, through 2011, Plumas County has opted to receive money from the Secure Rural Schools and Community Self-Determination Act instead of the Receipt Act. The amount of money generated by the Receipt Act is still determined because the Secure Rural Schools and Community Self-Determination Act is slated to expire at the end of the 2011 fiscal year. The Secure Rural Schools and Community Self-Determination Act is a "stop gap" measure to provide county public schools with federal funding. This act was created because of the lack of reliable timber receipts due to the current log market and erratic schedule of Forest Service timber sales. Congressional representatives are working to find a replacement of the Secure Rural Schools and Community Self-Determination Act but it is unknown what will come of this effort.

Revenue to the Government

Net revenue is the difference between the revenues generated by an alternative and the costs required to implement the alternative. In this analysis, revenues come from the harvest of saw timber and biomass.

Treatment Costs

Treatment or management costs include those costs associated with timber harvesting, biomass removal, road improvements, fuels treatments, and mitigation requirements, as well as costs of resource enhancement measures not associated with the sale of timber. Costs vary widely depending on the amount of mechanical, manual, or prescribed fire treatments; the board feet of sawlogs or tons of biomass removed per acre; and the accessibility of the treatment units.

Economic Consequences

Each of the action alternatives would create additional employment opportunities in service industries, such as logging supply companies, trucking companies, and fuel suppliers that serve the timber industry. There is also an induced effect that is driven by wages. Wages paid to workers by the primary and service industries would be circulated through the local economy for food, housing, transportation, and other living expenses.

All action alternatives would provide direct employment opportunities including jobs related to timber removal and forest fuel mitigation; and indirect employment opportunities such as fuel suppliers, lodging and local mechanics.

Alternative 2 – No Action

Direct and Indirect Effects of DFPZ and Area Thin Fuel Reduction Treatments, Improving Aspen and Cottonwood Growing Conditions and Providing Road Access to Meet Project Objectives while Reducing Transportation Effects

Implementation of Alternative 2, the No Action Alternative would have a negative effect on the local communities. Alternative 2 would negatively affect the local industries that rely on a steady supply of timber and service contracts to maintain community employment, as well as having a negative effect on Plumas County that would use the timber yield tax to fund county programs.

This alternative would not reduce critical fuel loadings or harvest any timber. No funds would be generated for the U.S. Treasury or returned to local communities (Table 27). Neither additional employment opportunities nor wages paid to primary or service industry employees would be circulated through the local economy. The local communities would not benefit from the 100 plus jobs that would be created and a potential loss in excess of $6 million dollars of employee-related income.

Cumulative Effects of No Action (Alternative 2)

Cumulative Effects DFPZ and Area Thin Fuel Reduction Treatments, Improving Aspen and Cottonwood Growing Conditions and Providing Road Access to Meet Project Objectives while Reducing Transportation Effects

The cumulative impact of the No Action Alternative would negatively affect local industries dependent on Forest Service contract work or a steady supply of timber, as well as communities that use the timber yield taxes to fund county programs. The local communities currently lack opportunities related to fuels reduction, site preparation, and timber harvest activities; the action alternatives would provide those opportunities. The local economy would also not receive benefits from associated employment, such as in food, lodging, and transportation businesses.

Throughout northern California, cumulative years of reduced timber harvesting activities (including those on Federal lands) have resulted in the loss of infrastructure to complete such activities. The loss of such infrastructure, including local mill closures, could significantly reduce or eliminate future economic and environmental opportunities from National Forest lands. The continuation of current conditions under Alternative 2 would preclude opportunities for long-term employment and rural community stability because the fuel reduction activities related to the creation and maintenance of DFPZ’s would not occur.

Alternative 1 – Proposed Action

Direct and Indirect Effects of DFPZ and Area Thin Fuel Reduction Treatments, Improving Aspen and Cottonwood Growing Conditions and Providing Road Access to Meet Project Objectives while Reducing Transportation Effects

Alternative 1 would generate approximately 6.6 million dollars in employee-related income, 165 full-time employment opportunities, and contribute 40,830 dollars in yield tax (Table 27). The total forest product value for Alternative 1 is estimate at just over $2 million dollars and calculated at 3 percent below the costs of implementing Alternative 1.

Table 27. Comparison of economic impacts by alternative for the Ingalls Project.

Revenue/ Cost/Employment	Alternative 1	Alternative 2	Alternative 3
Sawlog and biomass harvest revenues	$2,065,138	$0	$574,860
Total Cost	$2,118,360	$0	$1,465,350
Net harvest revenues	$(53,222)	$0	$(890,490)
Percent Above Timber Value	-3%	0%	-61%
Non-harvest costs (DFPZ construction)	$691,750	$0	$691,750
Total Project Value	($53,222)	$0	($890,490)
Timber yield tax	$40,830	0	$4,133
Receipt Act	$9,196	$0	$2,341
Harvest jobs	143	0	96
Service jobs	22	0	21
Total harvest and service jobs	165	0	117
Total employee-related income	$6,591,000	$0	$4,690,000

Alternative 3 – Non-Commercial Funding Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuel Reduction Treatments, Improving Aspen and Cottonwood Growing Conditions and Providing Road Access to Meet Project Objectives while Reducing Transportation Effects (Alternative 3)

Alternative 3 would generate over 4 million dollars in employee-related income, 117 full-time employment opportunities, and contribute 4,133 dollars in yield tax (Table 27). The total forest product value for Alternative 3 is estimated at 575 thousand dollars and calculated at 61 percent below the cost of implementing Alternative 3. Alternative 3 would create fewer jobs and generate less employee-related income than Alternative 1. Alternative 3 would generate $2,341 in Receipt Act payments.

Cumulative Effects of Action Alternatives

Cumulative Effects of DFPZ and Area Thin Fuel Reduction Treatments, Improving Aspen and Cottonwood Growing Conditions and Providing Road Access to Meet Project Objectives whle Reducing Transportation Effects (Action Alternatives)

Alternative 1 generates the most revenue for employees and in a time of economic downturn, the jobs created by the Ingalls Project would allow people to pay for basic expenses and potentially save for future investments. The revenue generated would stimulate local communities, benefit public schools and the local infrastructure for years to come. The other action alternative, Alternative 3, would result in similar cumulative effect by increasing the overall economic activity in the HFQLG Pilot Project area. However, part of the intent of the HFQLG Pilot Project is to create the greatest revenue and highest number jobs for Plumas, Lassen and Sierra counties. Alternative 1 would achieve this.

The amount of yield tax that private timber operators would provide to the State of California is lower in Alternative 3 at $4,133, and higher in Alternative 1 at $40,830. Alternative 2, the No Action Alternative provides no yield tax. Approximately 80 percent of the yield tax would be returned to Plumas County for various programs. The current economic downturn has had a negative effect on the school districts within Plumas County. These counties rely on timber tax receipts generated from Federal timber sales to support school programs.

Though it is not a requirement, it is assumed in the analysis that most forest products from HFQLG projects will be processed locally within Plumas, Lassen and Sierra counties due to high hauling costs to transport products out of the area. Likewise, it is also assumed most employment will be from residents of these counties due to the location of sawmills and cogeneration facilities. The Ingalls Project timber sale revenues and service contract employment would complement all other HFQLG funded projects across the forest. Economic goals for the project as a whole across the Pilot Project Area are discussed in the HFQLG Final Environmental Impact Statement.

Wildlife Biological Assessment/Biological Evaluation

Introduction

The purpose of this Biological Assessment/Biological Evaluation (BA/BE) is to determine whether the action alternatives would result in a trend toward listing or loss of viability for sensitive species, and to document effects on threatened, or endangered species and/or their critical habitat as part of determining whether formal or informal consultation with the United States Department of the Interior Fish and Wildlife Service (USFWS) is needed. This BA/BE is prepared in accordance with legal requirements set forth under Section 7 of the Endangered Species Act [19 U.S.C. 1536 (c), 50 CFR 402] and standards established in Forest Service Manual direction (FSM 2672.42).

Five categories of species are considered in this BA/BE; threatened, endangered, proposed, candidate and Forest Service sensitive species. Species federally listed as endangered by the USFWS are species currently in danger of extinction throughout all or a significant portion of their range. Species listed as threatened are likely to become endangered within the foreseeable future throughout all or a significant portion of their range. A proposed species is any species that is proposed in the Federal Register to be listed as a threatened or endangered species under the Endangered Species Act (ESA) (50 CFR 402.03). A candidate species is a species for which the USFWS has on file enough information to warrant or propose listing as endangered or threatened. Forest Service sensitive species are designated by the Regional Forester and are species that have known or suspected viability problems due to (1) significant current or predicted downward trends in population numbers or density, and/or (2) significant current or predicted downward trends in habitat quantity or quality for these species. The Forest Service considers the long-term conservation needs of sensitive species in order to avoid future population declines and the need for federal listing.

This BA/BE document consists of both a Biological Assessment for federally listed wildlife species potentially occurring on the PNF ("Federal Endangered and Threatened Species that may be affected by projects on the Plumas National Forest" updated April 29, 2010 (USFWS database, Appendix A)), and a Biological Evaluation for Region 5 Sensitive Species (updated October 15, 2007).

Several Threatened and Endangered (T&E) species identified in the list of T&E species provided by the "Federal Endangered and Threatened Species that may be affected by Projects in the Plumas National Forest", updated April 29, 2010, accessed via USFWS web page (http://www.fws.gov/sacramento/es/spp_lists/NFActionPage.cfm) (Appendix A), have been eliminated from further analysis, based on past analysis and concurrence from the USFWS (Rotta 1999, USFWS letter 1-1-99-I-1804 dated August 17, 1999) or due to lack of species distribution and/or lack of designated critical habitat. These species are listed below:

- Winter Run Chinook Salmon (*Oncorhynchus tshawaytsha*)

- Conservancy Fairy Shrimp (*Branchinecta conservatio*)
- Central Valley steelhead (*Oncorhynchus mykiss*)
- Delta Smelt (*Hypomesus transpacificus*)
- Lahontan cutthroat trout (*Oncorhynchus clarki henshawi*)
- Central Valley spring-run Chinook salmon (*Oncorhynchus tshawaytsha*)
- Carson wandering skipper (*Pseudocopaeodes eunus obscurus*)
- Critical Habitat for vernal pool invertebrates (Butte County)
- Critical Habitat for California Red-legged frog

In addition, the valley elderberry longhorn beetle, northern leopard frog, and Swainson's hawk, identified as Category 1 above, will not be further discussed because the habitat factors for these species are not in the wildlife analysis area; therefore, the project will not directly or indirectly affect these species or their habitat.

Hardhead minnow, California red-legged frog, northwestern pond turtle, greater sandhill crane and willow flycatcher, identified as Category 2 above, have habitat in the wildlife analysis area but will not be further discussed because the habitat factors for these species would not be either directly or indirectly affected by the project; therefore, the project will not affect these species or their habitat.

The species whose habitat would be either directly or indirectly affected by the Ingalls Project are carried forward in this analysis. This BA/BE report will evaluate the direct, indirect, and cumulative effects of the Proposed Action and alternatives on these species and their habitat.

Effects Analysis Methodology

The wildlife analysis area is defined as the project area (which includes the treatment areas) plus an additional larger land base. The additional larger land base was delineated based on the potential indirect and cumulative effects on California spotted owl Protected Activity Center (PAC) and Home Range Core Area (HRCA) distribution. The wildlife analysis area goes out to, and encompasses, the closest PACs/HRCAs to the project area. The wildlife analysis area totals approximately 38,901 acres of which 38,368 acres are on National Forest System lands. This wildlife analysis area is being used for all wildlife species analyzed in this BA/BE since the effects of the project to those species and their habitat would not extend beyond the wildlife analysis area boundary.

All direct, indirect and cumulative effects discussed, occur within this 38,368 acre wildlife analysis area. The direct and indirect effects of each alternative, together with the additive or cumulative effects of each alternative, have been considered in evaluating impacts to TES and TES habitat.

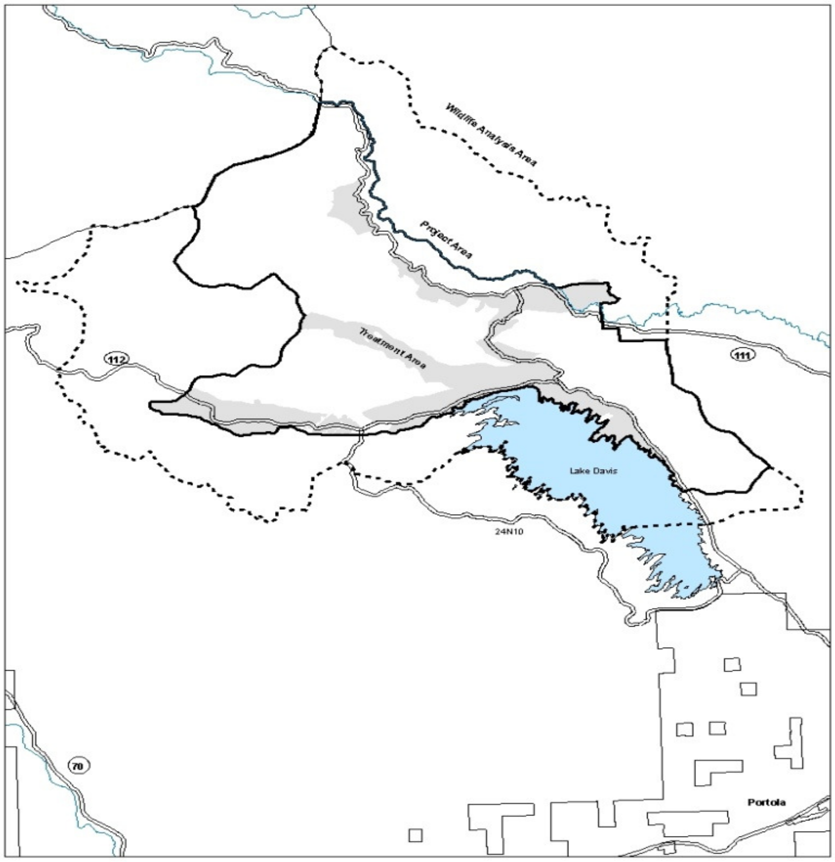

Figure 9 Ingalls Wildlife Analysis Area, Project Area and Treatment Area (solid color).

The Ingalls Project was reviewed on the ground, as well as, using aerial photographs, digital orthophoto quadrangles (DOQs), vegetation layer spatial datasets, species specific spatial datasets and known information to help determine suitable habitat for TES species (i.e. California spotted owls, northern goshawks, etc). In the field, areas identified as suitable habitat were surveyed to the following Region 5 protocols and acceptable standards.

Species nest sites and locations were recorded using Global Positioning System (GPS) and incorporated into spatial datasets. For the analysis of effects, changes to suitable habitat and impacts to protected activity centers (PACs)/territories were determined by using a spatial dataset of the vegetation layer combined with type of treatments.

Affected Environment/Environmental Consequences

Affected – Terrestrial Environment

The analysis of alternatives considers the attributes of structure and heterogeneity values for suitable habitat. Although these characteristics are evaluated, there is no standard for measurement. Therefore, the California Wildlife Habitat Relationships (CWHR) system continues to be used for wildlife habitat analysis for projects under the HFQLG FEIS as amended by the 2004 SNFPA FSEIS as it maintains consistency for monitoring changes in species habitat. This includes the requirement to not cumulatively reduce late seral dependent species habitat (5M, 5D, and 6) more than 10% below 1999 levels (USDA Forest Service 1999). These CWHR types have the highest probability of providing stand structures associated with preferred nesting, roosting and foraging.

For the comparative analysis contained in this BA/BE, the CWHR system is used to evaluate forest conditions and the suitability of wildlife habitat. This document uses CWHR size class 5 to differentiate late seral forest. California WHR size class 4 is considered mid-seral. The predominant CWHR size class of forest stands is 4, which accounts for approximately 81 percent of the wildlife analysis area (NF). California WHR size class 5 constitutes 6 percent of the wildlife analysis area (NF).

General Affected – Aquatic Environment

Within the wildlife analysis area there are 61 miles of perennial, 62 miles of intermittent and 216 miles of ephemeral streams for a total of 339 miles of streams. Of the 61 miles of perennial streams, approximately 44 miles are fish bearing. The main drainages within the wildlife analysis area include: Meadow Creek, Crystal Creek, Coldwater Creek, Poco Creek, Red Clover Creek, Big Grizzly Creek, Oldhouse Creek, Blakeless Creek, Paradise Creek, Love Joy Creek, and Little Grizzly Creek. Many of the small tributaries flowing into Red Clover Creek and Lake Davis originate from springs situated in their headwaters. All drainages in the project area flow into either Lake Davis or Red Clover. Grizzly and Red Clover Creeks are trout fisheries.

Environmental Consequences – Mountain and Foothill Yellow-Legged Frogs

The analysis of effects of the alternatives for these two species has been combined as proposed treatments have similar impacts to the aquatic environments where these species exist.

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

There would be no direct effects on YLF habitat, as no activities would occur that would cause disturbance to individual YLF, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of RHCAs and suitable YLF habitat.

Any acres burned at high intensity could contribute to increased sedimentation, which would adversely affect aquatic habitats and potential breeding habitat for the YLF.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen on the landscape thus potentially reducing habitat diversity in the wildlife analysis area, due to loss of the aspen clones and a cottonwood stand through succession (i.e., lack of stand recruitment and decadence of mature aspen) which would degrade the conditions for aquatic inhabitance.

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to decommission and/or reconstruct roads, or replace or install culverts. Roads causing resource damage would continue fragment the hydrology and aquatic habitat as well as contribute to poorer water quality.

Cumulative Effects for No Action

The No Action Alternative for the Ingalls Project would not protect or enhance YLF habitat. There would be no actions designed to reduce the risk of high intensity wildfire. There is the potential for RHCAs to act like chimneys and carry fire up and down the watershed.

Action Alternatives

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Direct effects include the killing or injuring of individuals from harvest machinery and burning activities. Harassment of individual frogs from thinning activity (e.g. noise disturbance and ground vibration) within or near habitat may also directly affect the species. Underburning could result in direct mortality of individuals if these activities are conducted during the period of time that overland movements may be going on.

Conifers in RHCAs would be treated to reduce the potential for large stand-replacing wildfire and release the remaining vegetation. The objective within the RHCAs (potential habitat for both species of yellow-legged frogs (YLFs)) is to maintain microclimate, protect stream banks from disturbance, and retain key attributes such as riparian vegetation, down logs and LWD recruitment.

To achieve the above objective, RHCAs would be designated on the ground and appropriate fuel treatments prescribed, based on RHCA characteristics and adjacent fuel treatments where slopes are ≤25%. Hardwoods would be retained in all units, except where removal is necessary for operability. Mechanical equipment would not enter the RHCA equipment exclusion zones (25 feet from the center of the stream channel along SMZs, 50 feet from the center of the stream channel along non-fish bearing RHCAs, and 100 feet from the center of the stream channel along fish bearing RHCAs), thus potential for direct impacts is negligible and very low risk. A backing fire would be allowed within RHCAs.

Within all RHCAs, burning intensities would be very light, due to restricted ignition within RHCAs and subsequent back burning, resulting in little consumption of LWD logs >12" dbh to meet the Soil Quality standards and guidelines retaining 10-15 tons per acre of LWD. Backburning would occur during times when there is increased moisture and potentially less consumption of LWD. Also, the "general burn plan" prescription is to consume fine fuels. Short-term sediment movement after burning may occur however; this depends on many factors such as slopes, fuel consumption, etc. A greater long-term benefit is the protection of the RHCAs from large stand-replacing wildfire. Again, applicable BMPs would be implemented.

There is a small potential for the modification of streamside vegetation and loss of duff layer due to prescribed fire in riparian areas. However, any impacts from prescribed fires are expected to be short lived. Fire intensity should be low enough to allow some retention of duff layer and riparian vegetation that would prevent soil erosion and expedite recovery.

Group selections would not occur within the RHCAs, although they may be located immediately adjacent to RHCAs, and certainly within the movement distances that MYLF may exhibit within lacustrine (lake/pond) environments. The suitability of the lacustrine environment is questionable due to the seasonal nature of the lacustrine environment and the presence of predatory fish in the wildlife analysis area.

Within the RHCAs, there is the potential for the following indirect effects: loss of sheltering habitat and riparian vegetation from backing fire, changes in the microclimate (reduced humidity, and increased air temperatures) due to the thinning and burning activities, and increased sedimentation to the stream channel to increased overland flows from the proposed project. Backing fires in the RHCAs and underburning in the uplands can increase sediment production in streams if buffer strips are not maintained (Chamberlin et al. 1991, USFWS 2001).

Annual water yields can be significantly increased after fire due to the reduction of transpiring vegetation (Agee 1993, USFWS 2001). Pile burning has essentially no direct effect on riparian vegetation since piles are typically placed outside of RHCAs. Since piles focus on removal of smaller sized fuels, existing larger diameter down woody debris would remain on site to provide for alternate sheltering and dispersal cover.

Vegetation management in the uplands can potentially change the hydrologic regime in the area. Soil erosion could direct sedimentation into streams that could create short-term unsuitable water quality that could disrupt habitat use by this species. However, with the implementation of SAT guidelines, RHCA buffers, sensitive area buffers, and Best Management Practices, it is anticipated that there would be no disruption in flows and minimal short-term sedimentation into streams (refer to CWE Report, Waterman 2011).

Habitat modifications as identified above, that are unfavorable to amphibians may favor their predators and increase the likelihood of further population declines due to unsustainable levels of predation (Knapp and Matthews 2000, Jennings and Hayes 1994). The perennial streams within the project area contain rainbow and brown trout, both known predators of yellow-legged frogs. Implementation of RHCAs, BMPs, and meeting Riparian Management Objectives would maintain suitable habitat conditions for trout in all streams they currently occupy.

All three species of garter snakes (*Thamnophis sp.*) that occur within the project area will feed on frogs, tadpoles and egg masses. Garter snake populations, especially those of the aquatic garter snake, are not expected to be affected by project activities.

Borax applied to stumps in either action alternative should not affect MYLFs or FYLFs.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

In the aspen thin units (Alternative 1), the ambient air temperature regimes would be restored through the removal of thick patches of conifer, and through enhanced aspen dominance. An overall slight reduction in aquatic temperatures is anticipated in a long-term perspective. Through increased water yield, reduced transpiration, increased diversity of understory and riparian vegetation, as well as increased canopy coverage derived from greater riparian vegetation growth water temperatures may be slightly reduced thus improving conditions for aquatic inhabitance.

Alternative 1 would restore approximately 150’ of stream channel in an aspen/cottonwood stand (Unit 003). This restoration could improve YLF habitat in this stream channel.

Direct and Indirect Effects of Providing Access to Meet Project Objects while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

Road closures would decrease compaction, increase percolation into the roadbed, increase soil stability and limit concentrated flow as well as surface erosion derived from temporary roads. All temporary skid roads would be treated with water bars, in addition to being closed to traffic by installation of dirt berms. New and temporary road construction would increase the potential for soil movement and increased potential sedimentation into streams and aquatic habitats.

The use of water for dust abatement by drafting water from creeks especially during the summer months may cause changes in the flow regimes and water quality, especially within deeper pools and off channel waterholes. Changes in flow regimes can result in changes in surface water elevations, exposing egg masses to air drying for short periods (early summer) to potentially longer periods of exposure later in the summer, resulting in loss of egg viability. There is also the potential for individual tadpoles, egg masses, or amphibians to be taken up by the “drafting” process, resulting in mortality of individuals. New or changes to existing water drafting sites would be evaluated by a biologist and hydrologist prior to changes and uses. As necessary, back down ramps would be maintained to ensure bank stability and sedimentation is minimized. Amphibian/fish protection devices such as suction strainer (2mm gauge or less) would be used during drafting operations to prevent entrainment of tadpoles, egg masses or amphibians.

Cumulative Effects for Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternatives evaluates the impact on TES habitat from the existing condition within the wildlife analysis area.

Future activities on National Forest System lands include ongoing work within the Freeman DFPZ and Grizz DFPZ. The Freeman and Grizz DFPZs have a similar design of actions as the Ingalls project (Alternative 1). These activities would maintain the existing condition of riverine and lacustrine habitat in the wildlife analysis area.

The grazing activity within the wildlife analysis areas is expected to continue into the future, therefore any effects to riparian habitats would continue.

The great gray owl habitat improvement project would have no effect on YLF habitat.

The fuelwood gathering and Christmas tree cutting programs on the PNF are ongoing programs that have been in existence for years and are expected to continue. The past and future effect of these actions has and would be to shift forest successional stages to somewhat earlier stages, while generally retaining continuous forest cover, which would have no affect on the YLFs.

Most of the recreation use within the wildlife analysis area consists of activities around Lake Davis and the developed camping/boat launch areas and include fishing, camping, picnicking, hiking, horseback riding, mountain biking, pleasure driving, OHV use, wildlife watching, hunting, firewood gathering. These same activities also occur dispersed throughout the wildlife analysis area by individuals and small groups. The use is expected to continue at the current rate. There is also a proposed trail project in the Lake Davis area, that would construct a 7.4 mile trail on the east and north sides of the lake for hiking and mountain biking. The construction of this project would construct bridges over streams and have mitigations in place to protect perennial and intermittent streams, thus it should not affect YLFs or their habitat.

Red Clover/Poco Watershed Project and the Red Clover/Poco Prop 50 watershed restoration work should improve riparian habitat on these stream channels, which could improve habitat for yellow-legged frogs.

The Blakeless Underburn project would have no effect on yellow-legged frog habitat.

The Plumas National Forest Public Motorized Traveled Management Project is currently underway. The outcome of the route designation process is not expected to result in additional cumulative effects as no new routes would be created; only existing unauthorized routes would be added to the system.

Environmental Consequences – Bald Eagle

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

There would be no direct effects on bald eagles or bald eagle habitat, as no activities would occur that would cause disturbance to nesting or foraging birds, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. The fuel loads that would be left by this alternative could make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable bald eagle nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. Thus potentially suitable habitat for a bald eagle territory could become patchy or unevenly distributed with this alternative, and could lead to reduced or lower abundance of bald eagles within the wildlife analysis area.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There are no aspen/cottonwood thin units in bald eagle habitat, therefore there would be no direct or indirect effects on bald eagles or bald habitat of not improving aspen/cottonwood stands.

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to decommission and/or reconstruct roads, or replace or install culverts. Roads causing resource damage would continue fragment the hydrology and aquatic habitat as well as contribute to poorer water quality.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls project would provide no long-term protection of bald eagle habitat from large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. Total wildfire acres and high intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted in SNFPA (USFS PSW, 2001)), which could lead to no potential habitat for eagles within the wildlife analysis area. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

Bald eagles exhibit great variation in response to human activity depending on the type, frequency, and duration of activity, modification of the physical environment, time of reproductive cycle, and individual bird accommodation to the disturbance (USDA Forest Service, 1977). The variable effects of human activity on the reproductive performance of bald eagles imply a threshold for detrimental impact between pristine isolation and habitat alteration.

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Potential direct effects on the bald eagle may result from the modification or loss of habitat or habitat components (primarily large trees, snags and other perches), and rarely from direct mortality if nest trees are felled. The action alternatives would not cut or remove nest trees or any large tree (≥30" dbh) that could be used for roosting or perching. Since bald eagles need large trees and have a preference for ponderosa pine, either of the action alternatives would enhance bald eagle habitat by thinning overstocked stands allowing for better growth and encouraging the regeneration of ponderosa pine.

Under both action alternatives there are approximately 300 acres of marginally suitable bald eagle habitat (WHR size class 4) with another approximately 600 acres being potentially suitable in the next 25 to 100 years. No currently suitable nesting habitat would be impacted with the implementation of either of the action alternatives. Both alternatives would release 65 acres of 715 acres in a primary use area and 1,086 acres of the 2,142 acres in secondary use areas through mechanical thinning. Of the 1,151 acres being released, dominant and co-dominant (20-30"dbh) trees would average an inch of growth every 5 years (personal comm. Beckwourth District Culturist). This would mean that 20 inch trees would reach suitable nesting size in 5 (21" dbh) to 50 years (30" dbh) instead of the 25 to 100 years if the stand went untreated.

In addition, disturbances associated with logging, temporary road building, or other associated activities within or adjacent to occupied habitat may disrupt nesting, fledging, and roosting activities. There is a low potential for smoke from burning piles, etc. to disrupt the normal behavior patterns of eagles using the area. Implementation of Limited Operating Periods (LOPs) around known bald eagle nests would remove the effects associated with direct disturbance on treatment units and temporary roads.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There are no aspen/cottonwood thin units in bald eagle habitat; therefore, there would be no direct or indirect effects on bald eagles or bald eagle habitat due to aspen/cottonwood thin.

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

Heavy recreation use on dirt roads would potentially cause increased sedimentation in streams, which decreases water quality (turbidity), which could impact foraging bald eagles. Reconstruction of existing roads may result in roads that are more accessible to general passenger vehicles and thus lead to a minor increase in recreational use of the area. New road construction would not likely result in an increase in recreational use, except perhaps by hunters in the fall. Construction of temporary roads would have no long-term impacts in the form of increased human use and presence in the area, but could lead to minor, temporary impacts in the form of increased sedimentation in streams and thus a decrease in water quality, which could negatively affect bald eagle foraging. However, changes in the fishery production are not expected as a result of implementing proposed fuel treatments (DFPZ). Implementation of BMPs and meeting all Riparian Management Objectives (RMO Analysis located in CWE report within project record) assures that there would be no indirect effects on the fisheries or fisheries habitat.

Cumulative Effects of Action Alternatives

The analysis of cumulative effects of the alternatives evaluates anticipated impact on TES wildlife from the existing condition (existing condition reflected by changes that have occurred in the past) within the wildlife analysis area. The past actions in the wildlife analysis area that contributed to the existing condition include grazing, timber harvest, prescribed burns, and recreation use.

Grazing is expected to continue at current levels. Grazing appears to have no cumulative effect on bald eagles since they have been breeding successfully for the last 25+ years in the Lake Davis area.

Future activities on National Forest System lands include ongoing work within the Freeman DFPZ and Grizz DFPZ. The Freeman and Grizz DFPZs have a similar design of actions as the Ingalls project (Alternative 1). The timber harvest activities in these projects would reduce the availability of old forest (CWHR Habitat 4M, 4D, 5M and 5D) stand structure and characteristics by approximately 0.3% or 184 acres out of 32,265 acres in the wildlife analysis area of the Grizz project and approximately 0.6 % or 379 acres out of 24,990 acres in the wildlife analysis area of the Freeman project. These projects would continue to implement measures from the BEHMA thus potentially improving habitat conditions for bald eagles.

The great gray owl habitat improvement project would have no effect on bald eagle habitat.

The fuelwood gathering and Christmas tree cutting programs on the PNF are ongoing programs that have been in existence for years and are expected to continue. The primary use areas in active bald eagle territories are protected from fuelwood gathering and Christmas tree cutting.

Most of the recreation use within the wildlife analysis area consists of activities around Lake Davis and the developed camping/boat launch areas and include fishing, camping, picnicking, hiking, horseback riding, mountain biking, pleasure driving, OHV use, wildlife watching, and hunting. The use is expected to continue at the current rate. There is also a proposed trail project in the Lake Davis area, that would construct a 7.4 mile trail on the east and north sides of the lake for hiking and mountain biking. The design and effects on the bald eagle habitat have not been analyzed. However, this could increase recreation opportunities in bald eagle primary and secondary use areas.

Red Clover/Poco Watershed Project and the Red Clover/Poco Prop 50 watershed restoration work are in Red Clover Valley, away from the primary nesting area for bald eagles, therefore they would have no direct effect on the eagles. However, both projects would improve riparian habitat on these stream channels, which could provide future foraging habitat for bald eagles.

The Blakeless Underburn project, within 2 miles of Lake Davis, would improve forest health and vigor and could therefore potentially provide the large tree component for future bald eagle habitat.

The Plumas National Forest Public Motorized Traveled Management Project is currently underway. The outcome of the route designation process is not expected to result in additional cumulative effects as no new routes would be created; only existing unauthorized routes would be added to the system.

Based on the direct, indirect and cumulative effects of the action alternatives, it is suspected that the overall potential nesting habitat in the wildlife analysis area would be improved. Improving future nesting habitat on the PNF would contribute to the PNF LRMP goal of 26 bald eagles territories on PNF lands, thus contributing to the overall Forest and State populations.

Environmental Consequences – California Spotted Owl

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

There would be no direct effects on spotted owl or spotted owl habitat, as no activities would occur that would cause disturbance to nesting or foraging birds, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. Only one large fire has been recorded in the Ingalls Project area. It was 447 acres and occurred in 1937, cause is unknown. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable owl nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. If a large fire occurred, suitable owl habitat could become patchy and could lead to reduced or lower abundance of owls within the wildlife analysis area.

Indicator Measure 2: Habitat components modified, lost or fragmented.

With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by spotted owls, especially during the nesting season, could cause disturbance that could disrupt and preclude successful nesting as well as the continued removal of current and future snags.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen on the landscape thus potentially reducing habitat diversity for spotted owls and their prey in the wildlife analysis area, due to lose of the aspen clone through succession (i.e., lack of stand recruitment and decadence of mature aspen).

Direct and Indirect Effects of Providing Access to meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to close and/or reconstruct roads, or replace or install culverts thus maintaining the current road density of approximately 2.8 miles/square mile. Roads causing resource damage would continue to fragment the hydrology and riparian habitat thus potentially reducing habitat diversity in the wildlife analysis area. All of which would decrease suitable habitat through disturbance and degradation.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls Project would not provide for the long-term protection of spotted owl habitat from large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. Total wildfire acres and high intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted in SNFPA (USFS PSW, 2001)), which could lead to lower owl abundance from existing condition within the wildlife analysis area. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

Wildlife Analysis Area

Potential direct effects on the spotted owl may result from the modification or loss of habitat or habitat components. Direct mortality could occur if nest trees are felled but this would be exceedingly rare. The action alternatives would not cut or remove nest trees. In addition, disturbances associated with logging, temporary road building, or other associated activities within or adjacent to occupied habitat may disrupt nesting, fledging, and foraging activities. Implementation of Limited Operating Periods (LOP) around known spotted owl nests would minimize the effects to existing owl pairs associated with direct disturbance on treatment units and access routes.

Based on the vegetation layer and the CWHR model, about 4.2 % or 1,618 acres within the wildlife analysis area (38,368 NF acres) may be considered suitable spotted owl nesting habitat (5M, 5D), and about 40.4 % or 15,484 acres may be considered suitable foraging habitat (4M and 4D).

Changes to suitable habitat as a result of implementing fuels treatments in Alternative 1 and 3 would occur due to the reduction in some canopy cover (below the minimum 40%) and the removal of needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) (Table 28). More specifically under Alternative 3 foraging habitat would be reduced through the removal of both the canopy cover (<40%) and the needed structural components, in all tree habitats, while nesting habitat would not be affected. Alternative 1 would reduce foraging habitat through the removal of the canopy cover (to 40%) in all eastside pine types (i.e. EPN, JPN and PPN tree habitat) in the DFPZ. All other tree habitat (mixed conifer and fir) and foraging habitat in the pine types in the area thin units treated under Alternative 1 would retain canopy cover at above 50% for suitable foraging habitat as well as the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.). This would be accomplished through variable density thinning which concentrates on retaining stand structure, both vertically and horizontally, (i.e. large tree radial thin, moderately dense stands and wildlife structural diversity patches in the HRCA). Alternative 1would convert 2 acres of nesting habitat through aspen thin treatments and change 42 acres of foraging habitat to size1 through group selection.

Blakesley (2003) states, “Nest success was positively associated with the presence of large remnant trees within the nest stand.” Ninety percent of the nest trees were greater than 76 cm dbh (30” dbh) and averaged 117 cm dbh (46” dbh). In addition to their value for nesting success, Moen and Gutierrez (1997) found that stands used by owls for roosting contained trees greater than 100 cm dbh (39” dbh) more frequently than randomly selected stands. The radial thinning treatments in Alternative 1 would retain and invigorate larger trees in the wildlife analysis area. Table 28 shows the above mentioned changes to California spotted owl nesting and foraging habitat by alternative within the wildlife analysis area.

Table 28. Comparison of Alternatives 1and 3 on Spotted Owl Nesting and Foraging Habitat (4M, 4D, 5M, 5D) within the Wildlife Analysis Area

Foraging Habitat	Alternative 1 (PA) Acres		% (Alt. 1) Remaining in Wildlife Analysis Area	Alternative 3 Acres		% (Alt. 3) Remaining in Wildlife Analysis Area
	Area Thin/ DFPZ/GS	Aspen Release		DFPZ		
4M	+243	-45	102%	-135		99.0%
4D	-285	-14	90.4%	-132		95.8%
Total Foraging Change (acres)	**-42**	**-59**	**99.3% retained (1.0%)**	**-267**		**98.3% retained (-2.0%)**
Nesting Habitat						
5M	+1	-2	99.8%	0		100%
5D	-1	0	99.9%	0		100%
Total Nesting Change (acres)	**0**	**-2**	**99.8% retained (-0.2%)**	**0**		**100% retained (0%)**

* Reductions shown here are due to the thinning of canopy and removal of the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) leading to unsuitable foraging and nesting habitat.
** Reductions shown here are due to the thinning of canopy below 40% in eastside pine types leading to unsuitable foraging and nesting habitat.

Alternative 1 reduces foraging habitat on 101 acres out of 15,484 acres, reduces nesting habitat on 2 acres out of 1618 acres; Alternative 3 reduces foraging habitat on 267 acres out of 15,484 acres and does not affect nesting habitat. Thus the amount of habitat retained post project (98.3-99.3% foraging and 99.8% - 100% nesting) allows opportunities for future dispersal, nesting and foraging within the wildlife analysis area.

Within the Ingalls project area, the action alternatives would result in an increase in low contrast fragmentation; that is dense canopy cover would be reduced within the DFPZ units but would maintain a continuity of large trees within treated stands and across the landscape. According to the 1993 CASPO IG EA (Page IV-81) (USDA Forest Service, 1993), within stand fragmentation of the small tree canopy (trees <20 to 30 feet) is less of a concern than large tree or old forest attributes removal because:

1. Historical understory densities were discontinuous;
2. This habitat component can return relatively quickly (versus large overstory layer); and
3. Creating this type of fragmentation can help avoid larger scale, high contrast fragmentation of forested stands caused by large stand-replacing wildfire.

The key to lessening impacts of fragmentation within DFPZ and Area Thin treatments is to maintain forest cover composed of the largest, fire resistant conifer species, while also providing structural attributes needed for prey species (snag/large logs, some smaller trees). Removal of trees up to 29.9” dbh would occur, with the overall objective of leaving enough dominant and co-dominant (20”-30” dbh) trees to provide from 40-50% canopy cover. This tree retention opens up the treated stand but does not isolate stands from surrounding forest or create habitat islands isolated by non-forest, thus increasing the likelihood for successful dispersal of wildlife.

Alternative 1 is designed to retain all of these attributes within DFPZ and Area Thin units while Alternative 3 would leave only the large tree attribute in DFPZ.

Group selection (Alternative 1) openings would create low-high density openings within stands, but each group would retain structural elements (if present) such as conifers over 30" dbh, hardwoods and down logs up to 10-15 tons/acre, that would reduce within stand fragmentation and contribute to decreasing the size of the forest opening. Group selection openings up to two acres meet the definition of continuous forest cover with the retention of all conifers over 30" dbh, 30 to 40 percent of the basal area consisting of the largest of the healthy trees and the largest snags, eight snags per acre (minimum of 20 square feet basal area of snags per acre) (USDA Forest Service, 1993). "This interpretation is made because group selection tends to mimic natural regeneration patterns and other harvests (intermediate harvests), while variable in appearance, tend to leave sufficient forest vegetation that a perception of continuous forest cover is maintained" (USDA Forest Service, 1993). This is the assumption used in the programmatic analysis for the HFQLGFRA FEIS (USDA Forest Service, 1999), assuming group selection harvest at a ten-year treatment cycle (5.7% of the land base) up to a 20-year treatment cycle (11.4% of the land base). Groups at this level could mimic naturally occurring gaps within forested stands. However, groups in the Ingalls project do not retain 30 to 40 percent of the basal area consisting of the largest of the healthy trees and the largest snags, eight snags per acre (minimum of 20 square feet basal area of snags per acre) as suggested by USDA Forest Service, 1993 due to our design of the group selections and the lack of large tree component across the Ingalls Project area.

The density of groups within stands potentially increases edge effects, reduces forest interior habitat, and creates a condition in which otherwise suitable owl habitat becomes less suitable because it is adjacent, and/or surrounded by, non-habitat. Franklin et al. (2000) found a positive relationship with the amount of edge between owl habitat and non-habitat and that Northern spotted owls showed higher reproductive success in sites with intermediate numbers of owl habitat patches intermixed with non-habitat areas. Blakesley (2003) on the other hand reported a model of reproductive output showing a weak negative relationship with elevation and amount of non-owl habitat within the nest area. It is unknown at what threshold the amount of edge to interior habitat results in use, marginal use or non-use by old forest species, including spotted owls. In terms of acres treated, Alternative 1 treats 42 acres of owl foraging habitat with groups. Alternative 3 has no group treatments identified in their actions.

Home Range Core Areas (HRCA)

The Record of Decision for the SNFPA FSEIS (2004) established HRCAs of 1,000 acres for each PAC for the Plumas National Forest. However, HFQLG activities were specifically excluded from the HFQLG standard and guidelines. The analysis of impacts to the HRCAs is still necessary to evaluate impacts to spotted owls and their habitat. Each HRCA is delineated within 1.5 miles of a nest site or activity center incorporating the best available contiguous habitat.

The closest comparable research on California spotted owls using this HRCA scale is found in Lee and Irwin (2005) who studied a HRCA of 1,062 acres (430 ha). Lee and Irwin (2005) concluded there was a possible minimum requirement for reproduction. Their research indicates the majority of nesting territories contained more than 50% intermediate (CWHR M) and dense (CWHR D) canopy cover, averaging 70% of the territory. Lee and Irwin fitted a logistical regression model to their data, which suggested a lower threshold of 56% of the territory with no increasing benefit to reproduction from additional amounts of intermediate and dense canopy cover. It is important to note that Lee and Irwin's study considered the effects of fuels treatments on California spotted owls. Table 29 shows the amount of suitable habitat within each approximately 1,000 acre home range core area (HRCA) potentially affected by the Ingalls project.

Table 29. Suitable Habitat (4M/4D/5M/5D) impacted within each 1,000 acre HRCA

HRCA	Acres of HRCA by CWHR type*		Total Acres in each HRCA	Current % of Suitable Habitat in each HRCA	Total Acres of Suitable Habitat Reduced in the HRCA			Total % Suitable Habitat Retained in the HRCA	
	Other - AGS, BAR, LAC, MCH, MCP, PGS, SGB, URB, WTM, 2D-S, 3D-S, 4P-S, 5P-S	Suitable Habitat 4M, 4D, 5M, 5D			Alt.1 Suitable Habitat 4M, 4D, 5M, 5D	Alt.3 Suitable Habitat 4M, 4D, 5M, 5D		Alt.1 % of Suitable Habitat Retained	Alt.3 % of Suitable Habitat Retained
PLU0137^	166	989	1,155	86	0	0		100	100
PLU0175^	273	798	1,071	75	-33	-23		96	97
PLU0096	216	838	1,054	80	0	0		100	100
PLU0242	274	830	1,104	75	0	0		100	100
Total All	**929**	**3,455**	**4,384**	**77**	**-33**	**-23**		**99**	**99**

^PACs in the Ingalls Project Area
***1** = Seedling Tree <1" dbh, **2** = Sapling Tree 1 - 6" dbh, **3** = Pole Tree 6 - 11" dbh, **4** = Small Tree 11 - 24"dbh, **5** = Medium/Large Tree >24"dbh, **6** = Multi-layered Tree.
D = Dense Canopy Cover (> 60%), **M** = Moderate Canopy Cover (40 - 59%), **P** = Open Canopy Cover (25 – 39%), **S** = Sparse Canopy Cover (10 – 24%), **AGS** = Annual Grassland, **BAR** = Barren, **LAC** = Lacustrine, **MCH** = Mixed Chaparral, **MCP** = Montane Chaparral, **PGS** = Perennial Grassland, **SGB** = Sagebrush, **URB** = Urban, **WTM** = Wet Meadow (Mayer and Laudenslayer 1988).

All four HRCAs are currently above the lower threshold of 56% necessary for reproduction suggested by Lee and Irwin (2005). Alternative 1 reduces suitable habitat on 33 acres out of 3,455 acres; Alternative 3 reduces suitable habitat on 23 acres out of 3,455 acres. Of the four owl HRCAs, both alternatives would retain 99% of the existing suitable habitat. Thus, the amount of habitat retained post project in the HRCAs allows opportunities for future nesting and foraging within the wildlife analysis area.

Home ranges of neighboring spotted owls commonly overlap (Verner et al. 1992: 149). The action alternatives that eliminate or modify habitat, possibly could cause a shift in owl home range use, increasing the potential for intraspecific competition between neighbors. The increased competition associated with using the same restricted habitat parcels could impact owl behavior, possibly affecting nesting and reproduction. Because of this, directly affected territories and

HRCAs could have an indirect affect on adjacent PACs/HRCAs not directly affected by the Proposed Action, especially if the directly affected territory or HRCA overlaps with another territory or HRCA. Only one HRCA would be affected by the Ingalls project and it is not directly adjacent to any other HRCA.

With a total reduction of 33 acres of suitable habitat in one HRCA with Alternative 1 (derived from and a total reduction of 23 acres of suitable habitat in one HRCA with Alternatives 3, it is anticipated that owl behavioral and competitive interactions will not be impacted. It is uncertain as to whether the same number of owl sites occupied in 2006 and 2007 (three and two) would be occupied within the wildlife analysis area post project. However, since PACs and SOHAs are avoided by treatments and the majority of the habitat within the 1,000 acre plus HRCAs would not be affected by treatments, it is reasonable to assume that occupancy would be maintained.

Nest Core

Several researchers have evaluated the spatial scale at which northern spotted owls respond to habitat (Hunter et al. 1995, Bingham and Noon 1997, Meyer et al. 1998, Franklin et al. 2000 and Zabel et al. 2003). Blakesley (2003) has provided insight into spatial availability of habitat for California spotted owls. Each of these studies found that areas within ~200 ha (500 acres) of nests were influential in determining occupancy and/or fitness. Blakesley (2003) states that occupancy, apparent survival, and nesting success all increased with increasing amounts of old-forest characteristics and that reproductive output decreased with increasing amount of non-habitat within the nest core area (nest core area = 203 ha scale, or 500 acres surrounding nest sites). Based on these studies, one could argue that management actions that reduce high-quality spotted owl habitat within a 500-acre area around known nests could present more risk to owls than activities occurring outside of this area. Each 500 acre nest core is a circular buffer around a nest site or activity center. No suitable habitat within any of the 500 acre nest cores would be affected by the Ingalls project.

Protected Activity Centers (PACs) and Spotted Owl Habitat Areas (SOHAs)

There are no 1,000 acre SOHAs and four 300 acre PACs located within the wildlife analysis area. PACs are designated from aerial photos and additional acres are the result of designating the best available habitat in relationship to geographical features and stand continuity. PACs are delineated based on guidelines provided in the SNFPA FEIS 2001 ROD and the SNFPA FSEIS 2004 ROD page 37. Where there is insufficient suitable habitat (6, 5D, 5M, 4D and 4M), to meet the 300 acre standard and guideline for a PAC, the next best vegetation sizes and types are included. No fuels treatments, including DFPZ, Area thin, group selection, or aspen thin treatments would occur within the designated 300 acre PACs. The four PACs equal approximately 1,406 acres owl habitat that would be retained and remain suitable within the wildlife analysis area on National Forest System lands.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Habitat Components

In terms of acres treated, with the subsequent potential for snag removal, Alternative 1 treats approximately 694 more acres than Alternative 3. Assuming equal distribution and density of snags across the wildlife analysis area, Alternative 3 would maintain more existing snags than the Proposed Action. However, Alternative 1 would maintain and/or improve structural diversity (large trees, hardwoods, downed wood, snags, snag recruitment, etc.) for wildlife while still maintaining DFPZ integrity.

Prey Species and Competitors

Fuel treatments including thinning and prescribed burning would result in a shift in stand microclimate that would have a negative impact to flying squirrels (Lehmkuhl et al. 2006). These treated stands would have fewer trees, a less complex and more open canopy structure (<50% canopy cover), resulting in a higher variability stand microclimate, all of which create more xeric conditions that would likely lower availability and biomass of truffles. Retention of down woody material and the largest trees may retain some level of lichen and truffle diversity and biomass, providing flying squirrel forage resources within treated stands. With regular maintenance through prescribed burning every 10 or so years, downed wood would be hard to retain in the long term, resulting in lower density of truffles. These potential losses would be offset by the benefit that fuel treatment could have for reducing the large-scale loss of habitat through wildfire. Less than 12% (3,401 to 4,095 of 38,368 acres) of the National Forest System lands within the wildlife analysis area would be treated with the Ingalls Project, while 34,967 to 34,273 acres of National Forest terrestrial forested habitat would not be treated. Location of treatment acres are constrained across the landscape for various resource reasons (PACs and SOHAS for example) such that this untreated habitat is spread across the wildlife analysis area and thus would unlikely impact the distribution and viability of flying squirrel populations.

It is unknown as to how some of the important prey species preferred by spotted owls (woodrats and flying squirrels) would respond to group selection harvest units. With reforestation, as the brush/seedling habitat matures, woodrats may recolonize sooner as they are known to utilize earlier successional habitats (CWHR Version 8.1, and G. Rotta, personal communication). Downed logs created by the retention of snags would provide down woody structures that would provide habitat for prey species. Flying squirrels would likely be absent within the group selection openings but could possibly utilize the edges to their advantage, and would eventually inhabit these areas as the forest matures. It is unknown if these small openings within the forest would be used for foraging by spotted owls. Reforestation should shorten the timeframe to develop forested stands as well as accelerate the development of old forest conditions that owls prefer when compared to natural succession.

Habitat modeling conducted for the SNFPA FEIS and subsequent FSEIS to project trends in woodrat and flying squirrel habitat as a result of implementing fuels reduction activities and group selection harvest within the Sierra Nevada range, indicated that populations of both species would apparently increase slightly over current conditions, but the difference in populations in either the short or long term would be very small.

Edges created by groups (Alternative 1) within suitable owl habitat may reduce the use of foraging habitat by spotted owls and may increase use by great horned owls, an effective competitor and predator of the spotted owl. Responses of prey species, as well as spotted owl use of group openings is one of the main objectives of the post implementation monitoring that would be conducted by PSW research through the administrative study. The post project monitoring would provide information as to the change in great horned owl use and occupancy and contribute knowledge as to the coexistence of these two species.

Borax applied to stumps in either action alternative should not affect California spotted owls, or avian and mammalian prey species.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

The aspen thin units (Alternative 1) would have a direct affect on spotted owl habitat with the removal of larger conifers (up to 29.9" dbh), 59 acres of foraging habitat and 2 acres of nesting habitat would be removed.

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

No new road construction would occur within PACs. Both alternatives propose to construct temporary road and utilize temporary roads, all of which would be closed post harvest. There would be no increase in habitat fragmentation with the temporary road construction, no temporary road construction would occur within PACs. In addition, road closures on some existing roads (Alternative 1) would create conditions to allow for vegetation recovery and reduce within stand gaps created by road openings. This should also reduce human activities that often lead to decreased habitat suitability for California spotted owls (snag and log removal thru woodcutting, and disturbance).

Open road density within the wildlife analysis area would decline under the Proposed Action from the existing approximately 2.8 miles/square mile to between 2.7 miles/square mile, which would slightly decrease habitat fragmentation.

Cumulative Effects of Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternatives evaluates the impact on TES habitat from the existing condition within the wildlife analysis area.

The action alternative in the Ingalls Project could contribute to a cumulative reduction in spotted owl nesting habitat. It is uncertain as to what influence these various reductions in habitat would have on owl activity and occupancy within the wildlife analysis area. As noted in the direct/indirect effects section, spotted owl PACs would not be entered for Ingalls Project activities, to conserve habitat for these species, and additional PACs and HRCAs would be created in the future, if warranted by new site-specific owl information.

Table 30. Cumulative Reduction of California Spotted Owl Nesting Habitat (5M, 5D) on Beckwourth Ranger District (RD)

Project	Red Clover DFPZ/GS	Dotta DFPZ/GS	Stony DFPZ/GS	Last Chance DFPZ/GS	Poison DFPZ/GS	Crystal-Adams DFPZ/GS**	Humbug DFPZ	Mabie DFPZ
	Alt. 3*	Alt. 2*	Alt. B*	Alt. 4*	Alt. 4*	Alt. 1*	Alt. 3*	Alt. 3*
Nesting Habitat	0 acres	0 acres	2 acres	0 acres	1 acre	0 acres	0 acres	0 acres
Project	Freeman DFPZ/GS	Old Sloat	Grizz DFPZ/GS	Cold Fire Recovery Project	Jackson DFPZ	Ingalls Project		
	Alt. 4*	Alt.1*	Alt. 4*	Alt. 1*	Alt. 3	Alt. 1	Alt. 3	Potential Cumulative Change
Nesting Habitat	379 acres	6 acres	184 acres	50 acres***	0 acres	2 acres	0 acre	**622 - 624 acres**

* Selected Alternative for the projects.
** Subsequent litigation dropped all group selections and applied a 12 inch upper diameter limit to the majority of the project area so the acres reflected in this table did not actually get reduced.
*** Reductions shown here are due to the removal moderate-high and high severity small pockets of roadside hazard trees in sections of mapped low and/or moderate vegetative burn severity and shows the worst case scenario.

Future activities on National Forest System lands include ongoing work within the Freeman DFPZ and Grizz DFPZ. The Freeman and Grizz DFPZs have a similar design of actions as the Ingalls project (Alternative 1). The timber harvest activities in these projects would reduce the availability of old forest (CWHR Habitat 5M and 5D) stand structure and characteristics by approximately 0.3% or 184 acres out of 32,265 acres in the wildlife analysis area of the Grizz project and approximately 0.6 % or 379 acres out of 24,990 acres in the wildlife analysis area of the Freeman project. These activities would contribute to a reduction of acres in late seral closed canopy coniferous forest habitat in the wildlife analysis area.

On-going grazing activities would have no effect on spotted owl habitat.

The great gray owl habitat improvement project would remove 146 acres of early and mid seral habitat, but would eventually help to increase late seral habitat.

With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by spotted owls, especially during the nesting season, could cause disturbance that could disrupt and preclude successful nesting as well as the continued removal of current and future snags

The recreation use at Lake Davis does not affect suitable spotted owl habitat. There proposed trail project in the Lake Davis area, that would construct a 7.4 mile trail on the east and north sides of the lake for hiking and mountain biking. Construction of this project would not affect spotted owl habitat.

Red Clover/Poco Watershed Project and Red Clover/Poco Prop 50 watershed restoration work would not affect spotted owl habitat.

The Blakeless Underburn project should improve forest health and vigor and could potentially provide spotted owl habitat in the future.

The Plumas National Forest Public Motorized Traveled Management Project is currently underway. The outcome of the route designation process is not expected to result in additional cumulative effects, as no new routes would be created; only existing unauthorized routes would be added to the system.

Environmental Consequences – Northern Goshawk

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

There would be no direct effects on northern goshawks or northern goshawk habitat, as no activities would occur that would cause disturbance to nesting or foraging birds, nor any impacts to the existing habitat conditions. Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. Only one large fire has been recorded in the Ingalls Project area. It was 447 acres and occurred in 1937, cause is unknown. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable goshawk nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. If a large fire, occurred suitable goshawk habitat could become patchy and could lead to reduced or lower abundance of goshawks within the wildlife analysis area.

Indicator Measure 2: Habitat components modified, lost or fragmented.

With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by northern goshawks, especially during the nesting season, could cause disturbance that could disrupt and preclude successful nesting as well as the continued removal of current and future snags.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen on the landscape thus potentially reducing habitat diversity for northern goshawks and their prey in the wildlife analysis area, due to lose of the aspen clone through succession (i.e., lack of stand recruitment and decadence of mature aspen).

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to close and/or reconstruct roads, or replace or install culverts thus maintaining the current road density of approximately 2.8 miles/square mile. Roads causing resource damage would continue to fragment the hydrology and riparian habitat thus potentially reducing habitat diversity in the wildlife analysis area. All of which would decrease suitable habitat through disturbance and degradation.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls Project would not provide for the long-term protection of northern goshawk habitat from large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. Total wildfire acres and high intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted in SNFPA (USFS PSW, 2001)), which could lead to lower owl abundance from existing condition within the wildlife analysis area. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

Wildlife Analysis Area

Potential direct effects on the northern goshawk may result from the modification or loss of habitat or habitat components, and rarely from direct mortality if nest trees are felled. The Proposed Action and alternatives would not cut or remove nest trees. In addition, disturbances associated with logging, temporary road building, or other associated activities within or adjacent to occupied habitat may disrupt nesting, fledging, and foraging activities (Richardson and Miller 1997). Implementation of Limited Operating Periods (LOPs) around known goshawk nests would remove the effects associated with direct disturbance on treatment units and access routes.

Proposed activities could cause short-term displacement and disruption during the time equipment is present and underburning activities are taking place if there are unknown nest sites unprotected by PACs and LOPs.

Based on the California Wildlife Habitat Relationships (CWHR) model, about 17,102 acres or 45% within the wildlife analysis area on National Forest System lands may be considered suitable goshawk nesting habitat (4M, 4D, 5M, 5D). In the wildlife analysis area, 1% is composed of 5D, 3% is composed of 5M, 8% is composed of 4D and 32% is composed of 4M. An additional 21% or 8,211 acres may be considered suitable foraging habitat on National Forest System lands in the wildlife analysis area. This wildlife analysis area encompasses 38,368 acres of National Forest System lands and was chosen in order to put habitat treatments within the context of the surrounding landscape. Uncertainty exists in the amount of nesting habitat that is actually available within the wildlife analysis area, but using vegetation layer mapped data provides consistency throughout this analysis.

In a recently published monograph on northern goshawks in the interior Pacific Northwest (McGrath et al. 2003), it was reported that goshawk nests occurred in the lower 1/3 of slopes and in drainage bottoms more than expected based on availability (and less than expected on the upper 1/3 slopes and ridgetops, although the upper 1/3 was not completely avoided but used half as often as would be expected based on the availability of such areas). The goshawk habitat for the wildlife analysis area was not stratified or analyzed using McGrath method because it is uncertain as to its application to goshawks in the Sierra Nevada, nor is the data available for the goshawk nest sites on the Plumas that would indicate whether nest sites fall into the McGrath parameters. This is pointed out to identify that the availability of goshawk habitat within the wildlife analysis area may potentially be overestimated.

Changes to suitable habitat as a result of implementing fuels treatments in Alternative 1 and 3 would occur due to the reduction in canopy cover (below the minimum 40%) and the removal of needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) (Table 31). More specifically, Alternative 1 in DFPZ's and Area Thin units would retain the minimum or more canopy cover for suitable foraging and nesting habitat as well as the needed structural components, except for eastside pine (EPN, JPN and PPN) habitats in the DFPZ. This would be accomplished through variable density thinning which concentrates on retaining stand structure (both vertically and horizontally) (i.e. large tree radial thin, moderately dense stands and wildlife structural diversity patches in the HRCA). Foraging and nesting habitat would be reduced through the removal of the canopy cover (to 40%) in the DFPZ in all eastside pine types (i.e.), but would retain needed structural components (snags, vertical and horizontal layering, down woody debris, etc.). Under Alternative 3 foraging habitat would be reduced through the removal of both the canopy cover (<40%) and the needed structural components, in all tree habitats, while nesting habitat would be reduced through the removal of the needed structural components in all tree habitats. Table 31 shows the changes to Northern goshawk nesting and foraging habitat by alternative.

Table 31. Comparison of Alternatives 1and 3 on Northern Goshawk Nesting (4M, 4D, 5M, 5D) and Foraging Habitat (3M, 3D, 4P, 5P) within the Wildlife Analysis Area

Forage Habitat	Alternative 1 (PA) Acres		% (Alt. 1) Remaining in Wildlife Analysis Area	Alternative 3 Acres		% (Alt. 3) Remaining in Wildlife Analysis Area
	DFPZ, Area Thin,GS	Aspen Release		DFPZ	Aspen Release	
3M	+16	-12	100%	+26	0	102%
3D	-126	-5	82.0%	-108	0	84.8%
4P	0	-4	100%	+267	0	104%
5P	0	0	100%	0	0	100%
Total Foraging Change (acres)	**-110**	**-21**	**98.4% retained (-2%)**	**+185**	**0**	**+102% retained (+2%)**
Nesting Habitat						
4M	+243	-45	102%	-135	0	99.0%
4D	-285	-14	90.4%	-132	0	95.8%
5M	+1	-2	99.9%	0	0	100%
5D	-1	0	99.9%	0	0	100%
Total Nesting Change (acres)	**-42**	**-61**	**99.4% retained (1.0%)**	**-267**	**0**	**98.4** In one territory, **% retained (-2%)**

* Reductions shown here are due to the removal of the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) leading to unsuitable foraging and nesting habitat.
** Reductions shown here are due to the thinning of canopy below 40% in pine types leading to unsuitable foraging and nesting habitat.

Alternative 1 reduces foraging habitat 131 acres out of 8,211 acre, reduces nesting habitat on 103 acres out of 17,102 acres; Alternative 3 increases foraging habitat 185 acres for a total of 8,396 acres and reduces nesting habitat on 267 acres out of 17,102 acres. In terms of habitat changes to 4D and 5D (assuming higher probability of goshawk use of these types), 99.9 to 100 percent of the CWHR 5D would be retained with action alternatives and 90.4 to 95.8 percent of CWHR 4D would be retained.

It is an unknown as to how some of the important prey species preferred by goshawks (small mammals, birds) would respond to opening up forested stands with DFPZ and group selection harvest units. Based on CWHR modeling, it is known that several bird species respond favorably to either less dense forested stands and/or openings within forested stands, while some do not (HFQLGFRA FEIS, Appendix I). The increased diversity and edges created by groups within forested stands may provide foraging habitat that would increase use of the landscape by goshawks. Responses of prey species, including small mammals and passerine bird use of group openings is one of the main objectives of the post implementation monitoring that would be conducted by PSW research through the administrative study. Post project monitoring would provide information as to the response by these prey species to DFPZ and group selection harvesting.

Borax applied to stumps in either action alternative should not affect northern goshawks, or avian and mammalian prey species.

Protected Activity Centers (PACs)

There are seven 200 acre PACs that are located within or overlap the wildlife analysis area. PACs are designated from aerial photos and additional acres are the result of designating the best available habitat in relationship to geographical features and stand continuity. PACs are delineated based on guidelines provided in the SNFPA FEIS 2001 ROD and the SNFPA FSEIS 2004 ROD page 38. Where there is insufficient suitable habitat (6, 5D, 5M, 4D and 4M), to meet the 200 acre guideline for a PAC, the next best vegetation sizes and types are included. Two goshawk PACs would be entered with the action alternatives. In one territory, both alternatives would thin 43 acres of 4D habitat retaining 50% or more of the canopy cover and structural habitat components therefore maintaining these acres as suitable nesting/foraging habitat. In the second territory, there are approximately 13 acres of ponderosa pine habitat (8 acres PPN4M, 5 acres PPN3M) that currently consist of nearly an all white fir understory. Alternative 1 would thin to remove some trees 12 -18” dbh to allow more sunlight to hit the ground to allow pine regeneration to occur, improving forest health on these acres which should improve goshawk habitat in the future. This territory would also have approximately 20 acres of pine type converted to aspen, which would improve biodiversity and goshawk foraging habitat.

Implementation of the action alternative during the nesting season around known nest sites could cause disturbance that could disrupt nesting behaviors and potentially lead to nest failure. The risk of this occurring is tempered by the delineation of a PAC around known nest sites and/or implementation of a LOP prohibiting disturbing activities from occurring within ¼ mile from nest sites.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Habitat Components

In terms of acres treated, with the subsequent potential for snag removal, Alternative 1 treats approximately 694 more acres than Alternative 3. Assuming equal distribution and density of snags across the wildlife analysis area, Alternative 3 would maintain more existing snags than the Proposed Action. However, Alternative 1 would maintain and/or improve structural diversity (large trees, hardwoods, downed wood, snags, snag recruitment, etc.) for wildlife, including goshawks and their prey, while still maintaining DFPZ integrity.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

Improving aspen habitat through thinning (Alternatives 1) may have short-term negative impacts but natural ecological recovery should reinvigorate the stand’s growth; thus these impacts should be short-lived with favorable long-term results to vegetation and stream health. The removal of conifers would promote sprouting leading to new younger trees with better growth, increase regeneration, and maintain or improve the current conditions thus potentially improving habitat diversity in the wildlife analysis area leading to more foraging opportunities for northern goshawks.

Direct and Indirect Effects of Providing Access to Meet Project Objectives andwhile Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

No new road construction would occur within PACs. Both alternatives propose to construct temporary road and utilize temporary roads, all of which would be closed post harvest. There would be no increase in habitat fragmentation with the temporary road construction, no temporary road construction would occur within PACs. In addition, road closures on some existing roads (Alternative 1) would create conditions to allow for vegetation recovery and reduce within stand gaps created by road openings. This should also reduce human activities that often lead to decreased habitat suitability for northern goshawks (snag and log removal thru woodcutting, and disturbance).

Open road density within the wildlife analysis area would decline under the Proposed Action from the existing approximately 2.8 miles/square mile to between 2.7 miles/square mile, which would slightly decrease habitat fragmentation.

Cumulative Effects of Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternatives evaluates the impact on TES habitat from the existing condition within the wildlife analysis area. Cumulative effects on the Northern goshawk are similar to those described for the California spotted owl on pages 63 – 64.

Cumulative effects on the goshawk could occur with the incremental loss of the quantity and/or quality of habitat for this species. Overall, increases in urbanization, increases in recreational use of Forest Service system lands, and the utilization of natural resources on state, private and federal lands may contribute to habitat loss for this species. High intensity stand replacement fires have contributed and would continue to contribute to loss of habitat for this species. Table 32 provides a cumulative total on the amount of suitable goshawk nesting habitat that has been impacted by the fuels treatments, group selection and area thinning projects implemented under HFQLG on the BKRD.

Table 32. Cumulative Changes (Reduction) in Northern Goshawk Nesting Habitat (4M, 4D, 5M, 5D, 6) on Beckwourth RD.

Project	Red Clover DFPZ/GS	Dotta DFPZ/GS	Stony DFPZ/GS	Last Chance DFPZ/GS	Poison DFPZ/GS	Crystal-Adams DFPZ/GS**	Humbug DFPZ	Mabie DFPZ
	Alt. 3*	Alt. 2*	Alt. B*	Alt. 4*	Alt. 4*	Alt. 1*	Alt. 3*	Alt. 3*
Nesting Habitat	1,574 acres	0 acres	230 acres	25 acres	35 acres	0 acres	0 acres	0 acres

Project	Freeman DFPZ/GS	Old Sloat	Grizz DFPZ/GS	Cold Fire Recovery Project	Jackson DFPZ	Ingalls Project		
	Alt. 4*	Alt.1*	Alt. 4*	Alt. 1***	Alt. 3	Alt. 1	Alt. 3	Potential Cumulative Change
Nesting Habitat	3,416 acres	125 acres	2,444 acres	68 acres	42 acres	103 acres	267 acres	**8,062 – 8,226 acres**

* Selected Alternative for the projects.
** Subsequent litigation dropped all group selections and applied a 12 inch upper diameter limit to the majority of the project area so the acres reflected in this table did not actually get reduced.
*** Reductions shown here are due to the removal moderate-high and high severity small pockets of roadside hazard trees in sections of mapped low and/or moderate vegetative burn severity and shows the worst case scenario.

The Ingalls project potentially contributes to a cumulative reduction in goshawk nesting habitat. It is uncertain as to what influence these various reductions in habitat would do to goshawk activity and occupancy within the wildlife analysis area. However, it is not anticipated that this cumulative habitat reduction would result in loss of occupancy or productivity of known goshawk PACs, based on the location of project activities to known PACs and the distribution of known PACs across the wildlife analysis area, and retention of at least 98% of available suitable nesting habitat distributed across the wildlife analysis area on National Forest System lands post project implementation.

Environmental Consequences – Great Gray Owl

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

There would be no direct effects on great gray owls or their habitat, as no activities would occur that would cause disturbance to nesting or foraging birds, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. Only one large fire has been recorded in the Ingalls Project area. It was 447 acres and occurred in 1937, cause is unknown. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable goshawk nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. If a large fire, occurred suitable great gray owl habitat could become patchy and could lead to reduced or lower abundance of great gray owls within the wildlife analysis area.

Indicator Measure 2: Habitat components modified, lost or fragmented.

With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by great gray owls, especially during the nesting season, could cause disturbance that could disrupt and preclude successful nesting as well as the continued removal of current and future snags.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen on the landscape thus potentially reducing habitat diversity for great grey owl and their prey in the wildlife analysis area, due to lose of the aspen clone through succession (i.e., lack of stand recruitment and decadence of mature aspen).

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to close and/or reconstruct roads, or replace or install culverts thus maintaining the current road density of approximately 2.8 miles/square mile. Roads causing resource damage would continue to fragment the hydrology and riparian habitat thus potentially reducing habitat diversity in the wildlife analysis area. All of which would decrease suitable habitat through disturbance and degradation.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls Project would not provide for the long-term protection of great gray owl habitat from large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. Total wildfire acres and high intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted in SNFPA (USFS PSW, 2001)), which could lead to lower owl abundance from existing condition within the wildlife analysis area. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

Wildlife Analysis Area

Potential direct effects on the great gray owl may result from the modification or loss of habitat or habitat components through thinning (reduce canopy cover and availability of future nest trees), and through underburning (snag/log and tree removal (safety hazards, etc.)). Disturbances associated with logging, temporary road building, or other associated activities within or adjacent to occupied habitat may disrupt nesting, fledging, and foraging activities. Implementing limited operating periods within 600 feet of occupied meadow habitats and restricting harvest activity within ½ mile of nest sites (if discovered) would reduce or completely eliminate potential disturbance impacts to this species from the Proposed Action.

Based on the vegetation layer and the CWHR model, about 2% or 646 acres within the Wildlife Analysis Area (38,368 acres) may be considered suitable great gray owl nesting habitat (4M, 4D, 5M, 5D, within 300 yards of a meadow) (USFS PSW, 2004), and about 2% or 659 acres may be considered suitable foraging habitat (meadows and open forested stands (CWHR S and P)).

Changes to suitable habitat as a result of implementing fuels treatments in both action alternatives would occur due to the removal of large structural components and reduction in canopy cover to 40 - 50%. The more open canopied forested stands still retain the minimum canopy cover for suitable habitat but become unsuitable due to the removal of the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.). DFPZ treatments will bring canopy cover down to 40%, the minimum to be classified as “M”, therefore the minimum to be considered foraging habitat. However, the removal of other important habitat components such as snags and vertical layering further diminish habitat value and render it unsuitable for foraging. Stands treated as Area Thin also decrease in habitat value due to a reduction in canopy cover to 50% and the removal of other important habitat components. There may also be some additional risk associated with isolated torching events during prescribed fire that could kill additional trees thus further opening up the canopy, and reducing foraging and nesting opportunities.

Alternative 1 reduces nesting habitat on 50 acres of 646 acres; Alternative 3 reduces nesting habitat on 45 acres of 646 acres. Thus the amount of nesting habitat retained post project would be 92.3% - 93.0% allows opportunities for future nesting within the wildlife analysis area.

Protected Activity Centers (PACs)

No preliminary PACs would be entered with the action alternatives. Implementation of the action alternatives during the nesting season around known nest sites could cause disturbance that could disrupt nesting behaviors and potentially lead to nest failure. The risk of this occurring is tempered by the delineation of a preliminary PAC and/or implementation of a LOP prohibiting disturbing activities from occurring within ¼ mile from nest sites.

Group selection openings created within the same watersheds as the existing suitable habitat could provide additional foraging habitat. Project activities are not expected to result in indirect effects, nor are they expected to create conditions that would not allow for occupancy and establishment of a great gray owl territory around the suitable meadow habitat within the project area.

Borax applied to stumps in either action alternative should not affect great gray owls, or avian and mammalian prey species.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Habitat Components

In terms of acres treated, with the subsequent potential for snag removal, Alternative 1 treats approximately 694 more acres than Alternative 3. Assuming equal distribution and density of snags across the wildlife analysis area, Alternative 3 would maintain more existing snags than the Proposed Action. However, Alternative 1 would maintain and/or improve structural diversity (large trees, hardwoods, downed wood, snags, snag recruitment, etc.) for wildlife while still maintaining DFPZ integrity.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

One of the aspen thin units (Alternative 1) is within suitable gray owl habitat because it is a meadow aspen stand. Removing conifers < 30” in size from the meadow would help to maintain the aspen and meadow habitat, which is important for foraging great gray owls. It is expected that short-term negative impacts may occur but natural ecological recovery should reinvigorate the stand’s growth; thus, these impacts should be short-lived with favorable long-term results to vegetation and meadow health. In meadow type aspen stands, the removal of conifers not only helps to regenerate aspens but also helps to stop the conversion of meadow habitat to forest habitat thus potentially improving foraging habitat for great gray owls.

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

No new road construction would occur within PACs. Both alternatives propose to construct temporary roads and utilize temporary roads, all of which would be closed post harvest. There would be no increase in habitat fragmentation with the temporary road construction, no temporary road construction would occur within PACs. In addition, road closures on some existing roads (Alternative 1) would create conditions to allow for vegetation recovery and reduce within stand gaps created by road openings. This should also reduce human activities that often lead to decreased habitat suitability for great gray owls (snag and log removal thru woodcutting, and disturbance).

Open road density within the wildlife analysis area would decline under the Proposed Action from the existing approximately 2.8 miles/square mile to between 2.7 miles/square mile, which would slightly decrease habitat fragmentation.

Cumulative Effects of Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternatives evaluates the impact on TES wildlife from the existing condition within the Wildlife Analysis Area. The past actions in the Wildlife Analysis Area that contributed to the existing condition include grazing, timber harvest, watershed restoration, and recreation use.

Cumulative effects on the great gray owl could occur with the incremental loss of the quantity and/or quality of habitat for this species. Overall, increases in urbanization, increases in recreational use of Forest Service system lands, and the utilization of natural resources on private and federal lands may contribute to habitat loss for this species. High intensity stand replacement fires have contributed and would continue to contribute to loss of habitat for this species.

No matter what alternative is chosen for the Ingalls project, grazing is expected to continue at current levels. There are five grazing allotments that overlap into the wildlife analysis area, of which two are inactive. Of the three active allotments, two are in the Lake Davis area and overlap the great gray owl habitat and preliminary PAC, Grizzly Valley Community and Grizzly Valley. Approximately 77 percent of the Grizzly Valley Community allotment is within the wildlife analysis area, 277 cow/calf pairs are authorized from June 16 through September 30. Approximately 35 percent of the Grizzly Valley allotment is within the wildlife analysis area, 505cow/calf pairs are authorized from June 16 through September 15. This activity would continue to impact meadow vegetation thus potentially affecting prey species (voles and pocket gophers) abundance and availability due to the lack of suitable breeding, foraging and hiding cover.

The great gray owl habitat improvement project would remove 146 acres of early and mid seral habitat, but would eventually help to increase late seral habitat. This project is designed to provide future great gray owl nesting habitat.

The fuelwood gathering and Christmas tree cutting programs on the PNF are ongoing programs that have been in existence for years and are expected to continue. With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by great gray owls, especially during the nesting season, could cause disturbance that could disrupt and preclude successful nesting as well as the continued removal of current and future snags.

The recreation use at Lake Davis will be on going and any impacts to great gray owl habitat would likely continue. The proposed trail project in the Lake Davis area, that would construct a 7.4 mile trail on the east and north sides of the lake for hiking and mountain biking. Construction of this project would not affect great gray owl habitat.

Red Clover/Poco Watershed Project and Red Clover/Poco Prop 50 watershed restoration work could provide future suitable great gray owl foraging habitat in Red Clover Valley.

The Blakeless Underburn project should improve forest health and vigor and could potentially provide future great gray owl nesting habitat.

The Plumas National Forest Public Motorized Traveled Management Project is currently underway. The outcome of the route designation process is not expected to result in additional cumulative effects as no new routes would be created; only existing unauthorized routes would be added to the system. Table 33 provides a cumulative total on the amount of suitable great gray owl nesting habitat that has been impacted by the fuels treatments, group selection and area thinning projects implemented under HFQLG on the BKRD.

Table 33. Cumulative Changes (Reduction) in Great Gray Owl Nesting Habitat on the Beckwourth RD.

Project	Red Clover DFPZ/GS	Dotta DFPZ/GS	Last Chance DFPZ/GS	Poison DFPZ/GS	Crystal-Adams DFPZ/GS**	Humbug DFPZ	Mabie DFPZ
	Alt. 3*	Alt. 2*	Alt. 4*	Alt. 4*	Alt. 1*	Alt. 3*	Alt. 3*
Nesting Habitat	0 acres	0 acres	25 acres	35 acres	0 acres	0 acres	0 acres
Project	Freeman DFPZ/GS	Grizz DFPZ/GS	Ingalls Project				
	Alt. 4*	Alt. 4*	Alt. 1	Alt. 3	Potential Cumulative Change		
Nesting Habitat	1,882 acres	605 acres	50 acres	45 acres	2,532 – 2,537 acres		

Ingalls project potentially contributes to a cumulative reduction in great gray owl nesting habitat. It is uncertain as to what influence these various reductions in habitat would do to great gray owl activity and occupancy within the Wildlife Analysis Area. However, it is not anticipated that this cumulative habitat reduction would result in loss of occupancy or productivity of the preliminary great gray owl PACs, based on no entry into preliminary PACs, the location of project activities to preliminary PACs, and retention of at least 92% of available suitable nesting habitat distributed across the Wildlife Analysis Area on National Forest lands post project implementation.

Environmental Consequences – Mesocarnivores (Pacific Fisher, American Marten, Sierra Nevada Red Fox, and California Wolverine)

Alternative 2 – No Action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

There would be no direct effects on mesocarnivores or mesocarnivore habitat, as no activities would occur that would cause disturbance to denning/resting or foraging mesocarnivores, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential loss of suitable owl nesting habitat and other important habitat attributes such as large trees, large snags and down woody material. If a large fire occurred suitable mesocarnivore habitat could become patchy within the wildlife analysis area.

With the current PNF woodcutting program, the project area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by mesocarnivores, especially during the denning season, could cause disturbance that could disrupt and preclude successful denning.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen on the landscape thus potentially reducing habitat diversity for mesocarnivores and their prey in the wildlife analysis area, due to lose of the aspen clone/cottonwood stand through succession (i.e., lack of stand recruitment and decadence of mature aspen).

Direct and Indirect Effects of Providing Access to Meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

There would be no action taken to close and/or reconstruct roads, or replace or install culverts thus maintaining the current road density of approximately 2.8 miles/square mile. Roads causing resource damage would continue to fragment the hydrology and riparian habitat thus potentially reducing habitat diversity in the wildlife analysis area. All of which would decrease suitable habitat through disturbance and degradation.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls Project would not provide for the long-term protection of mesocarnivore habitat from large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. Total wildfire acres and high intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted in SNFPA (USFS PSW, 2001), which could lead to the loss of existing habitat within the wildlife analysis area. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales

Indicator Measure 2: Habitat components modified, lost or fragmented.

Wildlife Analysis Area

A population is defined as a group of individuals of the same species occupying a defined area at the same time (Hunter 1996). Regarding Sierra Nevada Red Fox, wolverine, and possibly the fisher, all of which have very large home ranges, the PNF would probably contribute to the population within the Sierra Nevada mountain range, if individuals were found on the Forest. However, due to the lack of suitable habitat (subalpine conifer (SCN)) and verified sightings across the Plumas NF the Ingalls project would not affect the red fox or wolverine.

Numerous systematic surveys using various accepted methodologies, spatially conducted over 65% of the PNF since the mid 1980's, indicate that the Plumas does not now contribute to the Sierra Nevada populations of these two forest carnivores; they are either non-existent or in such small numbers that the known detection methodologies are inadequate to determine presence. As stated earlier, a male fisher has been tracked on the west side of the Plumas, but did not stay, and the reintroduced population is more than 40 miles from the Ingalls project area. A small population of marten exists on the Plumas, located within the Lakes Basin area on the Plumas/Tahoe NF border. Martens have been detected within the proposed Big Hill Project area but well outside of the Ingalls wildlife analysis area. Based on known detections of marten on the PNF, no changes in marten occupancy or distribution on the PNF should occur as a result of the Ingalls project.

Potential direct effects on these carnivores from vegetation management activities consist of modification or loss of habitat or habitat components, especially in regards to denning/resting habitat and foraging/travel habitat. Additional direct effects are possible behavioral disturbance to denning from logging, road building, or other associated activities (refer to HFQLGFRA BA/BE).

Changes to suitable habitat as a result of implementing fuels treatments in Alternatives 1 and 3 would occur due to the reduction in canopy cover (some below the minimum 40%) and the removal of needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) (Table 34). More specifically under Alternative 1 denning habitat would be reduced through the removal of the canopy cover (<60%) in all eastside pine types (i.e. EPN, JPN and PPN tree habitat) in the DFPZ. In OFEH and all other tree habitat (mixed conifer and fir) in the DFPZ treated under this alternative suitable habitat would retain the minimum canopy cover for foraging and denning habitat as well as the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.). This would be accomplished through variable density thinning which concentrates on retaining stand structure Alternative 3 would reduce foraging and denning habitat through the removal of both the canopy cover (<40%) and the needed structural components, in all tree habitats. Table 34 shows the above mentioned changes to American marten and Pacific fisher denning and foraging habitat by alternative.

Table 34. Comparison of Alternatives 1 and 3 on American Marten and Pacific Fisher Suitable Habitat (4M, 4D, 5M, 5D) within the Wildlife Analysis Area

Foraging Habitat	Alternative 1 (PA) Acres		% (Alt. 1) Remaining in Wildlife Analysis Area	Alternative 3 Acres		% (Alt. 3) Remaining in Wildlife Analysis Area
	*DFPZ, Area Thins, GS	Aspen Release		**DFPZ,	Aspen Release	
4M	+243	-45	102 %	-135	0	99.0 %
5M	+1	-2	99.9 %	0	0	100 %
Total Foraging Change (acres)	**+244**	**-47**	**102 % retained (+2%)**	**-135**	**0**	**99% retained (-1.0 %)**
Denning Habitat						
4D	-285	-14	90.4 %	-132	0	95.8 %
5D	-1	0	99.9 %	0	0	100 %
Total Denning Change(acres)	**-286**	**-14**	**91.6 % retained (-8.4 %)**	**-132**	**0**	**96.3 % retained (- 3.7 %)**

* Reductions shown here are due to the thinning of canopy below 40% in pine types leading to unsuitable foraging and denning habitat.
**Reductions shown here are due to the removal of the needed structural components (snags, vertical and horizontal layering, down woody debris, etc.) leading to unsuitable foraging and denning habitat.

Based on the vegetation layer, about 9.3% or 3,579 acres within the wildlife analysis area on National Forest System lands (38,368 NF acres) may be considered suitable denning habitat (4D and 5D), and about 35% or 13,523 acres may be considered suitable foraging habitat (4M and 5M). For marten and fisher habitat, Alternative 1 reduces denning habitat on 300 acres of 3,579 acres, but increases foraging habitat on 244 acres for a total of 13,767 acres; Alternative 3 reduces denning habitat on 132 acres of 3,579 acres and reduces foraging habitat on 135 acres of 13,523 acres. Retention of conifer trees >30” dbh, and retention of all hardwoods would provide structural attributes selected by marten and fisher for denning and resting sites. Down woody debris would be retained at 10-15 tons/acre in the largest logs. Snags would be retained at three to six snags per acre.

Zielinski et al. (2004) reported that fisher used large trees, large conifer snags and large hardwoods supporting cavities or platforms for rest sites, and suggested that fishers require multiple resting structures distributed throughout their home ranges. Zieleinski et al. suggested that “managers can maintain resting habitat for fishers by favoring the retention of large trees and the recruitment of trees that achieve the largest sizes”. With both action alternatives, no trees over 30” dbh would be removed, four of the largest snags per acre would be maintained (except group selections) and hardwoods would be retained. Conifers retained possessing one or more of the following characteristics that are of value for wildlife: large limbs extending into the openings and meadows; mistletoe brooms higher than 20’ from the ground; multiple tops; bole sweep; broken tops; heart rot; snags; etc would decrease the risk of deleterious effects to old-forest related wildlife over the Ingalls project area in the long term (Dunk, 2005).

It is an unknown as to how some of the important prey species preferred by marten and fisher (small mammals, birds) would respond to group selection harvest units. The increased diversity and edges created by groups within forested stands may provide increased foraging opportunities for marten and fisher. Responses of prey species, including small mammals and passerine bird use of group openings and DFPZs is one of the main objectives of the administrative study conducted by PSW.

Borax applied to stumps in either action alternative should not affect mesocarnivores, or avian and mammalian prey species.

Direct and Indirect Effects of Aspen and Cottonwood Treatments

Indicator Measure 3: Change in vegetation and stand characteristics.

Improving aspen habitat through thinning (Alternative 1) may have short-term negative impacts but natural ecological recovery should reinvigorate the stand's growth; thus these impacts should be short-lived with favorable long-term results to vegetation and stream health. The removal of conifers would promote sprouting, leading to new younger trees with better growth, increase regeneration, and maintain or improve the current conditions thus potentially improving habitat diversity in the wildlife analysis area leading to more foraging opportunities for mesocarnivores.

Direct and Indirect Effects of Providing Road Access to meet Project Objectives while Reducing Transportation System Effects

Indicator Measure 4: Changes in road density.

Both alternatives propose to construct temporary road and utilize temporary roads, all of which would be closed post harvest. There would be no increase in habitat fragmentation with the temporary road construction. In addition, actions including road closure on some existing roads (Alternative 1) and on new temporary roads (both alternatives), would create conditions to allow for vegetation recovery and reduce within stand gaps created by road openings. This should also reduce human activities that often lead to decreased habitat capability for carnivores (snag and log removal thru woodcutting, and disturbance).

Open road density within the wildlife analysis area would decline under the Proposed Action from the existing approximately 2.8 miles/square mile to between 2.7 miles/square mile, which is still providing for low habitat capability for forest carnivores. Overall this would slightly decrease habitat fragmentation.

Cumulative Effects of Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternatives evaluates the impact on TES habitat from the existing condition within the wildlife analysis area. Cumulative effects on the Mesocarnivores are similar to those described for the California spotted owl on pages 64-65.

Cumulative effects on forest carnivores could occur with the incremental reduction of the quantity and/or quality of habitat for this species. Overall, increases in urbanization, increases in recreational use of Forest Service system lands, and the utilization of natural resources on state, private and federal lands may contribute to habitat loss for this species. Moderate-high and high severity large stand-replacing fires have contributed and would continue to contribute to loss of habitat for these species.

The Ingalls project potentially contributes to a cumulative reduction in suitable fisher and marten habitat. It is uncertain as to what influence these various reductions in habitat would do to potential future fisher and marten activity and occupancy within the wildlife analysis area. These cumulative reductions are not expected to increase large scale, high contrast fragmentation above existing levels.

Table 35. Cumulative Change (Reduction) of Pacific Fisher and American Marten Denning Habitat (4D, 5D, 6) on Beckwourth RD.

Project	Red Clover DFPZ/GS	Dotta DFPZ/GS	Stony DFPZ/GS	Last Chance DFPZ/GS	Poison DFPZ/GS	Crystal-Adams DFPZ/GS**	Humbug DFPZ	Mabie DFPZ
	Alt. 3*	Alt. 2*	Alt. B*	Alt. 4*	Alt. 4*	Alt. 1*	Alt. 3*	Alt. 3*
Denning Habitat	1,255 acres	0 acres	230 acres	25 acres	26 acres	0 acres	127 acres	375 acres
Project	Freeman DFPZ/GS	Old Sloat	Grizz DFPZ/GS	Cold Fire Recovery Project	Jackson DFPZ	Ingalls Project		
	Alt. 4*	Alt.1*	Alt. 4*	Alt. 1***	Alt. 3	Alt. 1	Alt. 3	Potential Cumulative Change
Denning Habitat	1,549 acres	13 acres	429 acres	34 acres	630 acres	300 acres	132 acres	**4,825 – 4,993 acres**

*Selected Alternative for the projects.
** Subsequent litigation dropped all group selections and applied a 12 inch upper diameter limit to the majority of the project area so the acres reflected in this table did not actually get reduced.
*** Reductions shown here are due to the removal moderate-high and high severity small pockets of roadside hazard trees in sections of mapped low and/or moderate vegetative burn severity and shows the worst case scenario.

The fisher does not currently inhabit the HFQLG area and even though reintroduction has begun just west of the Plumas National Forest, it would probably be several more years before available habitats would become fully occupied (Facka, per. com). Based on the home range and stand size reported in the April 8, 2004 Federal Register, it appears as if the wildlife analysis area supports large blocks of contiguous suitable habitat. Based on studies of home range sizes referenced in the above-mentioned Federal Register, estimates of potentially suitable and contiguous habitat that must be present before an area can sustain a population of fishers range from 31,600 acres in California, 39,780 acres in the northeastern United States, and 64,000 acres in British Columbia. Based on the vegetation layer and GIS, it appears as if the Ingalls project does not meet this acreage figure under existing conditions, 17,102 acres of 4M, 4D, 5M, 5D, 6 habitats on National Forest System lands (38,368 acres) in the wildlife analysis area. Thus the Ingalls project area most likely does not support habitat attributes needed to contribute to the potential for recovery of the species in this area of the PNF.

Since no California wolverines or Sierra Nevada red fox are believed to exist in, or near, the wildlife analysis area, no direct, indirect or cumulative impacts are expected for the California wolverine and Sierra Nevada red fox.

Environmental Consequences – Bats (Pallid Bat, Townsend's Big-eared Bat, and Western Red Bat)

Alternative 2 – No action Alternative

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 2)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

There would be no direct effects on bats or bat habitat, as no activities would occur that would cause disturbance to denning bats, nor any impacts to the existing habitat conditions.

Indirect effects of no action include the potential for future wildfire and its impact on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead to increased rates of spread resulting in potential modification of suitable bat habitat including the loss of large trees, large snags and down woody material.

Direct and Indirect Effects of Aspen and Cottonwood Treatments (Alternative 2)

Indicator Measure 3: Change in vegetation and stand characteristics.

There would be no action taken to maintain and restore aspen/cottonwood on the landscape thus potentially reducing habitat diversity in the wildlife analysis area, due to lose of the aspen clone/cottonwood stand through succession (i.e., lack of stand recruitment and decadence of mature aspen). Stream channel restoration and planting of cottonwood plugs would not occur; therefore no improvement to western red bat habitat would occur

Direct and Indirect Effects of Providing Road Access while Reducing Transporation System Effects (Alternative 2)

Indicator Measure 4: Changes in road density.

There would be no action taken to close and/or reconstruct roads, or replace or install culverts, both of which do not provide habitat. Roads causing resource damage would continue fragment the hydrology and aquatic habitat thus potentially reducing habitat diversity in the wildlife analysis area.

Cumulative Effects of No Action

The No Action Alternative for the Ingalls Project would not provide long-term protection of bat habitat from being greatly altered by a large stand-replacing fire. There would be no actions designed to reduce the risk of high intensity wildfire. There would be no thinning that could enhance the growth of dominant and co-dominant (20”-30” dbh) trees that may provide future habitat availability.

Action Alternatives

The implementation of Management Area direction and habitat prescriptions and allocations for California spotted owl, northern goshawk, forest carnivores, and willow flycatchers, including the retention of large trees, retention of hardwoods, snags and LWD and maintaining aquatic/riparian ecosystem processes, would provide many of the habitat attributes necessary to support the sensitive bat species. Potentially suitable habitat may exist within the project area for all three of these bat species (Pallid, Townsend’s big-eared and Western red bats).

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Action Alternatives)

Indicator Measure 1: Acres of suitable habitat modified, lost or fragmented at various scales.

Indicator Measure 2: Habitat components modified, lost or fragmented.

Direct effects from the proposed activities are possible if any of these species occurs in the project area. Destruction of active roosts through felling or removal of small trees with hollows could displace or harm individual bats. Chain saw activity or the use of heavy equipment causing ground vibrations may cause noise and tremor disturbance significant enough to cause temporary or permanent roost abandonment resulting in lowered reproductive success. These effects would be most severe during the breeding season (May 20 to August 15) when the potential exists for disturbance to active breeding females and maternity colonies. If any of these sensitive bat species breed in the area, project activities during the breeding season could affect individual bats, including direct mortality.

These bats have been known to utilize large conifer snags and tree hollows as day roosting sites, so some roosting habitat may be lost. Habitat attributes such as large live trees, and large snags could be removed or modified by the action alternatives. Hazard trees, including snags, along the road, and those removed for safety reasons, could result in direct mortality of bat species that may be roosting within the tree or snag. However, with both action alternatives no trees over 30” dbh would be removed, four to six of the largest snags per acre would be maintained (except group selections) and all hardwoods would be retained. The promotion of black oaks through the black oak radial thin would benefit Pallid and Townsend’s big-eared bats roosting and foraging opportunities. Conifers retained possessing one or more of the following characteristics that are of value for wildlife: large limbs extending into the openings and meadows; mistletoe brooms higher than 20’ from the ground; multiple tops; bole sweep; broken tops; heart rot; snags; etc; all habitat attributes that provide for bat roosting and/or foraging habitat.

Due to the small size of bats, and the difficulty of surveying for them, it is hard to determine where they are roosting. Because they are insectivores, removal of logs may reduce the amount of microhabitat available for wood boring beetles that may be utilized as prey.

There would be no habitat disruption of or modification to rock outcrops, caves and mining adits. No man-made structures that could provide habitat for bats are planned for removal or modification, other than roads and culverts, both of which do not provide habitat.

As part of a strategic system of defensible fuel profile zones, this project would reduce the potential for high-severity wildfires, which could eliminate vast tracts of habitat for these species. Prey base for bats (insects) may have some site-specific short-term reductions post underburning due to direct mortality of eggs, larvae, pupae and adults from fire. However, post-fire conditions have been shown, in many instances, to increase plant vigor (Lyon and Stickney 1976, DeByle 1984, Stein et al. 1992). It has also been shown that many herbivore insects preferentially feed on and have increased reproductive success and fitness on more vigorous plants and plant parts, "the plant vigor hypothesis" (Price 1991, Spiegel and Price 1996). Therefore, post fire conditions may increase the forage base available to bats.

Direct and Indirect Effects of Aspen and Cottonwood Treatments (Action Alternatives)

Indicator Measure 3: Change in vegetation and stand characteristics.

The removal of conifers would promote sprouting leading to new younger trees with better growth, increase regeneration, and maintain or improve the current conditions thus potentially improving habitat diversity in the wildlife analysis area leading to increased foraging and roosting opportunities for all three of these bat species (Pallid, Townsend's big-eared and Western red bats). Planting of cottonwood plugs is planned in unit 003, as part of stream channel restoration, to help promote growth of new cottonwoods in this stand. Should these plugs take, it would provide habitat in the future for these bat species, especially western red bats that use cottonwood leaves for roosting.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transporation System Effects (Action Alternatives)

Indicator Measure 4: Changes in road density.

Both alternatives propose to construct temporary roads and utilize temporary roads, all of which would be closed post harvest. There would be no increase in habitat fragmentation with the temporary road construction. In addition, road closures on some existing roads (Alternative 1) would create conditions to allow for vegetation recovery and reduce within stand gaps created by road openings. This should also reduce human activities that often lead to decreased habitat suitability for all three of these bat species (Pallid, Townsend's big-eared and Western red bats) (snag and log removal thru woodcutting, and disturbance). Overall this would slightly decrease habitat fragmentation.

Cumulative Effects of Action Alternatives

The existing condition reflects the changes of all activities that have occurred in the past. The analysis of cumulative effects of the action alternative evaluates the impact on TES wildlife from the existing condition within the wildlife analysis area.

No populations of sensitive bat species are known to occur in the wildlife analysis area, but based on surveys conducted across the Forest in various habitats, their presence is suspected. Cumulative effects on bats could occur with the incremental loss of the quantity and/or quality of habitat for these species. Overall, increases in urbanization, increases in recreational use of National Forest System lands, and the utilization of natural resources on state, private and federal lands may contribute to habitat loss for these species.

With the current PNF woodcutting program, the wildlife analysis area would be open to public woodcutting 12 months a year, limited only by available access. Uncontrolled public use within the areas used by bats, especially during the breeding season (maternity roosts), could cause disturbance that could disrupt and preclude successful recruitment of young as well as remove roost trees.

Summary of Determinations

See Table 36 for a summary of the determinations.

Table 36. Determinations of Effects on Threatened, Endangered, Proposed, and Sensitive Animal Species that Potentially Occur on the Plumas National Forest

Species	Action Alternatives*	Alternative 2* (No Action)
AMPHIBIANS		
Foothill yellow-legged frog (*Rana boylii*)	MAI	WNA
Sierra (Mountain) yellow-legged frog (*Rana sierrae*)	MAI	WNA
BIRDS		
Bald eagle (*Haliaeetus leucocephalus*)	MAI	WNA
California spotted owl (*Strix occidentalis occidentalis*)	MAI	WNA
Northern goshawk (*Accipiter gentilis*)	MAI	WNA
Great Gray Owl (*Strix nebulosa*)	MAI	WNA
MAMMALS		
American marten (*Martes americana*)	MAI	WNA
Pacific fisher (*Martes pennant pacifica*)	MAI	WNA
California wolverine (*Gulo gulo luteus*)	WNA	WNA
Sierra Nevada red fox (*Vulpes vulpes necator*)	WNA	WNA
Pallid bat (*Antrozous pallidus*)	MAI	WNA
Townsend's big-eared bat (*Corynorhinus townsendii*)	MAI	WNA
Western red bat (*Lasiurus blossevillii*)	MAI	WNA

*__Determinations:__ **T, E & P Species: WNA** = Will Not Affect, **MAINLA** = May Affect but Is Not Likely to Adversely Affect Individuals or their designated critical habitat, **MAILAA** = May Affect and Is Likely to Adversely Affect Individuals or their designated critical habitat.

Management Indicator Species (MIS)

Introduction

The purpose of this report is to evaluate and disclose the impacts of the Ingalls Project on the eleven (11) Management Indicator Species (MIS) identified in the Plumas National Forest (NF) Land and Resource Management Plan (LRMP) (USDA Forest Service 1988) as amended by the Sierra Nevada Forests Management Indicator Species Amendment (SNF MIS Amendment) Record of Decision (USDA Forest Service 2007). This report documents the effects of the Proposed Action and alternatives on the habitat of selected project-level MIS. Detailed descriptions of the Ingalls Project alternatives are found in Chapter 2 of the Ingalls Project Environmental Assessment (EA) (USDA Forest Service 2011). Implementation could begin as early as summer, 2012. All activities proposed would be completed within approximately five to eight years.

MIS are animal species identified in the SNF MIS Amendment Record of Decision (ROD) signed December 14, 2007, which was developed under the 1982 National Forest System Land and Resource Management Planning Rule (1982 Planning Rule) (36 CFR 219). Guidance regarding MIS set forth in the 1988 Plumas LRMP as amended by the 2007 SNF MIS Amendment ROD directs Forest Service resource managers to (1) at project scale, analyze the effects of proposed projects on the habitat of each MIS affected by such projects, and (2) at the bioregional scale, monitor populations and/or habitat trends of MIS, as identified in the 1988 LRMP as amended.

Effects Analysis Methodology

Geographic Analysis Areas

The treatment area is defined as the units to be treated, between 3,401 and 4,095 acres. The project area is defined as the treatment area plus an additional larger land base, which equals approximately 17,909 acres. This project area is located at elevations ranging from 5,400 feet along Red Clover Creek to 8,319 feet at the top of Mt Ingalls. For the purpose of this MIS report, the wildlife analysis area is defined as the project area (which includes the treatment areas) plus an additional larger land base. The additional larger land base was delineated based on the potential indirect and cumulative effects on California spotted owl Protected Activity Center (PAC) and Home Range Core Area (HRCA) distribution. The wildlife analysis area goes out to and encompasses the closest PACs/HRCAs to the project area. The wildlife analysis area totals approximately 38,901 acres, of which 38,368 acres are on National Forest System lands. This wildlife analysis area is being used for all wildlife species analyzed in this MIS report since the effects of the project to those species and their habitat would not extend beyond the wildlife analysis area boundary.

All direct, indirect and cumulative effects discussed, occur within this 38,368 acre Wildlife Analysis Area. The direct and indirect effects of each alternative, together with the additive or cumulative effects of each alternative, have been considered in evaluating impacts to MIS and MIS habitat.

Specific Methodology

The Ingalls Project was reviewed on the ground and using aerial photographs, digital orthophoto quadrangles (DOQs), vegetation layer spatial datasets, species specific spatial datasets and known information to help determine the potential presence of MIS species (i.e. Mule deer, Hairy woodpeckers, etc.). In the field, while conducting protocol surveys for TES species, any observations of MIS species are documented on 1:24000 scale quad maps. Species nest sites and locations are then incorporated into spatial datasets based on the mapped locations or Global Positioning System (GPS) points. For the analysis of effects, changes to suitable habitat were determined by using a spatial dataset of the vegetation layer combined with type of treatments (i.e. mechanical thinning, group selection, aspen thin, grapple pile, mastication, etc).

Affected Environment/Environmental Consequences

General Affected Environment

For the comparative analysis contained in this MIS Report, the CWHR system is used to evaluate habitat conditions and the suitability of wildlife habitat. Table 4 in the MIS Report displays all pre-treatment vegetation information currently available within the Wildlife Analysis Area. All vegetation information is displayed using the CWHR vegetation codes. The vegetation layer is a composite of remote sensed data and local project specific vegetation data all based on aerial photo interpretation.

General Environmental Consequences

Cumulative Impacts of actions on MIS Habitat or Ecosystem Components

The cumulative changes in MIS habitat or ecosystem components as a result of implementing silvicultural treatment as per action alternatives are displayed for the Wildlife Analysis Area in Table 37.

Table 37. Summary of Changes in Ingalls Wildlife Analysis Area Pre and Post Action Alternatives Treatment on MIS Habitat acres.

Habitat or Ecosystem Component	Pre-treatment MIS Habitat - Acres (Alt.2 – No Action)	Post Treatment MIS Habitat - Acres (Alt.1)	Change in MIS Habitat - Acres	Post Treatment MIS Habitat - Acres (Alt.3)	Change in MIS Habitat - Acres
Early Seral Coniferous Forest	3,736	3,769	+33	3736	0
Mid Seral Coniferous Forest	24,000	23,877	-123	24,000	0
Late Seral Open Canopy Coniferous Forest	285	285	0	285	0

Habitat or Ecosystem Component	Pre-treatment MIS Habitat - Acres (Alt.2 – No Action)	Post Treatment MIS Habitat - Acres (Alt.1)	Change in MIS Habitat - Acres	Post Treatment MIS Habitat - Acres (Alt.3)	Change in MIS Habitat - Acres
Late Seral Closed Canopy Coniferous Forest	1,618	1,616	-2	1,618	0
Hardwood/conifer	32	32	0	32	0
Riparian	295	295	0	295	0
Riverine & Lacustrine	2,597	2,597	0	2,597	0
Shrubland (west-slope chaparral types)	559	559	0	559	0
Wet Meadow	1,153	1,153	0	1,153	0
CWHR not included in MIS Habitat	4,093	4,186	+93	4,093	0
Grand Total	**38,368**	**38,368**	**0**	**38,368**	**0**

Effects of the Proposed Project on the Habitat for the Selected Project-Level MIS

Early and Mid-Seral Coniferous Forest Habitat (Mountain quail)

Effects of Alternative 2 (No Action)

Direct, Indirect, and Cumulative Effects to Habitat

There would be no direct or indirect effects on early and mid seral coniferous forest habitat, as no activities would occur that would impact the existing habitat conditions, thus there would also be no additional cumulative effects as a result of selecting this alternative. As a result, existing early and mid seral coniferous forest conditions and mountain quail habitat conditions would be maintained.

Cumulative Effects Conclusion

It is anticipated that implementation of the No Action Alternative, in combination with present and reasonably foreseeable future actions, would not have a cumulative effect to the population and habitat distribution across the Plumas National Forest. Thus existing early and mid seral coniferous forest conditions and mountain quail habitat conditions would be maintained.

Effects of the Action Alternatives

Direct and Indirect Effects to Habitat

Changes under each action alternative would be very nominal. Alternative 3 would have no net change in early or mid seral coniferous forest habitat while Alternative 1 would type convert 17 acres of early seral and 74 acres of mid seral coniferous forest habitat to aspen habitat, thus creating healthier growing conditions for the aspen by reducing shading (subsequently increasing sunlight to aspen) and increasing the water available to the aspen. Alternative 1 also increases early seral habitat by 42 acres and reduces mid seral habitat by 42 acres through the implementation of group selections. Overall, the amount of early and mid seral coniferous habitat retained post project would be 99.7% (Alternative 1) and 100% (Alternative 3) within the Wildlife Analysis Area.

Cumulative Effects Conclusion

It is anticipated that implementation of the action alternatives, in combination with present and reasonably foreseeable future actions would increase the amount of early and mid seral coniferous forest habitat while the removal of snags would not affect these habitats within the Wildlife Analysis Area. These changes will not alter the existing trend in the early and mid seral coniferous forest habitat.

Relationship of Project-Level Habitat Impacts to Bioregional-Scale Mountain Quail Trend

The direct/indirect and cumulative effects of the Ingalls Project would have a nominal affect on the amount and/or distribution of early and mid seral habitat within the Wildlife Analysis Area. However, this change in the amount of early and mid seral habitat in the Wildlife Analysis Area will not alter the existing trend in the habitat, nor will it lead to a change in the distribution of mountain quail across the Sierra Nevada bioregion

Late Seral Closed Canopy Coniferous Forest Habitat (California spotted owl and Northern flying squirrel)

Effects of Alternative 2 (No Action)

Direct, Indirect, and Cumulative Effects to Habitat

There would be no direct or indirect effects on late seral closed canopy coniferous forest habitat, as no activities would occur that would impact the existing habitat conditions, thus there would also be no additional cumulative effects as a result of selecting this alternative. As a result, existing late seral closed canopy coniferous forest conditions and California spotted owl/northern flying squirrel habitat conditions would be maintained.

Cumulative Effects Conclusion

It is anticipated that implementation of the No Action Alternative, in combination with present and reasonably foreseeable future actions, would not have a cumulative effect to the population and habitat distribution across the Plumas National Forest. Thus, existing late seral closed canopy coniferous forest conditions and California spotted owl/northern flying squirrel habitat conditions would be maintained.

Effects of the Action Alternatives

Direct and Indirect Effects to Habitat

Changes under each action alternative would be very nominal. Alternative 3 would have no effect on late seral closed canopy coniferous forest habitat while Alternative 1 would decrease the amount of late seral closed canopy coniferous forest habitat by 2 acres through the implementation of aspen/cottonwood enhancement. Thus, the amount of late seral closed canopy coniferous forest habitat retained post project for Alternative 1 would be 99.9% within the Wildlife Analysis Area.

Cumulative Effects Conclusion

It is anticipated that implementation of the Alternative 1, in combination with present and reasonably foreseeable future actions, would decrease the amount of late seral closed canopy coniferous forest habitat within the Wildlife Analysis Area. However, the affected area is small 2 acres for this project), thus, these changes will not alter the existing trend in the late seral closed canopy coniferous forest habitat.

Relationship of Project-Level Habitat Impacts to Bioregional-Scale Trends

California spotted owl

The direct/indirect and cumulative effects of the Ingalls Project would have a nominal affect on the amount and/or distribution of late seral closed canopy coniferous forest habitat within the Wildlife Analysis Area. However, this change in the amount of late seral closed canopy coniferous forest habitat in the Wildlife Analysis Area will not alter the existing trend in the habitat, nor will it lead to a change in the distribution of California spotted owls across the Sierra Nevada bioregion.

Northern flying squirrel

The direct/indirect and cumulative effects of the Ingalls Project would have a nominal affect on the amount and/or distribution of late seral closed canopy coniferous forest habitat within the Wildlife Analysis Area. However, this change in the amount of late seral closed canopy coniferous forest habitat in the Wildlife Analysis Area will not alter the existing trend in the habitat, nor will it lead to a change in the distribution of northern flying squirrels across the Sierra Nevada bioregion.

Riparian Habitat (Yellow warbler)

Effects of Alternative 2 (No Action)

Direct, Indirect, and Cumulative Effects to Habitat

There would be no direct or indirect effects on riparian habitat, as no activities would occur that would impact the existing habitat conditions, thus there would also be no additional cumulative effects as a result of selecting this alternative. As a result, existing riparian habitat conditions and yellow warbler habitat conditions would be maintained.

Cumulative Effects Conclusion

It is anticipated that implementation of the No Action Alternative, in combination with present and reasonably foreseeable future actions, would not have a cumulative effect to the population and habitat distribution across the Plumas National Forest. Thus existing riparian habitat conditions and yellow warbler habitat conditions would be maintained.

Effects of the Action Alternatives

Direct and Indirect Effects to Habitat

Alternative 3 has no direct or indirect affect on riparian habitat in the Wildlife Analysis Area. However, Alternative 1 would directly affect 150' of stream channel in an aspen/cottonwood stand through stream channel restoration. This project would stabilize eroded streambanks, treat headcuts, and revegetate the streambanks. Indirectly this project would improve water quality due to reduced sedimentation and improve riparian vegetation growing conditions (Waterrman 2011). This alternative would also indirectly affect 95 acres or 32% of the riparian habitat within the Wildlife Analysis Area as a result of habitat modification (removing conifers). Overall, indirect effects from removing conifers from areas surrounding riparian habitat should allow for the flourishing of willow/aspen/cottonwood type vegetation. This would be accomplished by allowing more sunlight to reach plants and the forest floor, plus more water availability with less conifer competition.

Cumulative Effects Conclusion

It is anticipated that implementation of the action alternatives, in combination with present and reasonably foreseeable future actions would maintain the amount of riparian habitat by removing competing conifers, while the removal of snags would not affect these habitats within the Wildlife Analysis Area. These changes will not alter the existing trend in the riparian habitat.

Relationship of Project-Level Habitat Impacts to Bioregional-Scale Yellow Warbler Trend

The direct/indirect and cumulative effects of the Ingalls Project would have no affect on the amount and/or distribution of riparian habitat within the Wildlife Analysis Area. Since there will be no affect, the Ingalls Project will not alter the existing trend in the habitat, nor will it lead to a change in the distribution of yellow warblers across the Sierra Nevada bioregion.

Riverine & Lacustrine Habitat (Aquatic Macroinvertebrates)

Effects of Alternative 2 (No Action)

Direct, Indirect, and Cumulative Effects to Habitat

Selection of the No Action Alternative would contribute to no direct or indirect effects to riverine and lacustrine habitats, thus there would also be no additional cumulative effects because of selecting this alternative. Therefore, there would be no direct, indirect or cumulative impacts to riverine and lacustrine habitats. As a result, existing riverine and lacustrine habitat conditions and aquatic macroinvertebrate habitat conditions would be maintained.

Cumulative Effects Conclusion

It is anticipated that implementation of the No Action Alternative, in combination with past, present and reasonably foreseeable future actions, would not have a cumulative effect to the population and habitat distribution across the Plumas National Forest. Thus, existing riverine and lacustrine conditions and aquatic macroinvertebrate habitat conditions would be maintained.

Effects of the Action Alternatives

Direct and Indirect Effects to Habitat

No Riparian Habitat Conservation Areas (RHCAs) or Streamside Management Zones (SMZs) equipment exclusion zones would be directly impacted by equipment operations during harvest/thinning activities. Under Alternative 1 approximately 150’ of stream channel in an aspen/cottonwood stand would be affected through stream channel restoration. This project would stabilize eroded streambanks, treat headcuts, and revegetate the streambanks. Indirectly this project would improve water quality due to reduced sedimentation and improve riparian vegetation growing conditions (Waterman 2011).

Flow

Streams within the Wildlife Analysis Area are not expected to change flow due to the implementation of the action alternatives. For example, all perennial streams are expected to remain perennial, all intermittent streams are expected to remain intermittent, and the same for ephemeral streams. Flow will change depending on the water year. The existing flow condition should remain the same post treatment unless a large water event occurs, thus affecting the existing macroinvertebrate habitat.

Water surface shade (Waterman 2011)

The canopy cover in RHCAs will be greater than 40 percent. This would allow stream shading during the early summer months when many streams are flowing, maintain moister microclimates for fish and macroinvertebrates and stream temperatures would not be affected. In addition to reducing the risk of high-intensity fires, thinning RHCAs will allow the ecosystem within this corridor to return to a more productive historic condition. Through increased water yield, reduced transpiration, increased diversity of understory and riparian vegetation, as well as increased canopy coverage derived from greater riparian vegetation growth, water temperatures may be slightly reduced thus improving conditions for sensitive aquatic macroinvertebrates.

Sediment (Waterman 2011)

Increased sediment delivery could result in changes to stream channel morphology, water quality, and downstream fish habitat. Factors within sediment regimes such as timing, volume, and character of sediment input and transport will be more consistent with those conditions under which the riparian and aquatic ecosystems developed. It is anticipated with these treatments that stream channel integrity, channel processes and sediment regimes will more closely represent historic conditions.

Cumulative Effects Conclusion

It is anticipated that implementation of the action alternatives, in combination with present and reasonably foreseeable future actions would maintain the amount and improve the quality of riverine and lacustrine habitat by reducing conifer competition, improving overall riparian vegetation vigor and maintaining water surface shade within the Wildlife Analysis Area. These changes will not alter the existing trend in the riverine and lacustrine habitat. Thus existing riverine and lacustrine conditions and aquatic macroinvertebrate habitat conditions would be maintained.

Relationship of Project-Level Habitat Impacts to Bioregional-Scale Aquatic Macroinvertebrates Habitat Trend

The direct, indirect and cumulative effects of the Ingalls Project would not alter the amount riverine and lacustrine habitats within the Wildlife Analysis Area. There would be no change in the amount of riverine and lacustrine habitats in the Wildlife Analysis Area therefore the Ingalls Project will not alter the existing trend in the habitat, nor will it lead to a change in the distribution of aquatic macroinvertebrates across the Sierra Nevada bioregion.

Snags in Green Forest Ecosystem Component (Hairy woodpecker)

Effects of Alternative 2 (No Action)

Direct, Indirect, and Cumulative Effects to Habitat

Selection of the No Action Alternative would contribute to no direct or indirect effects to snags in green forest habitat, thus there would also be no additional cumulative effects as a result of selecting this alternative. Therefore, there would be no direct, indirect or cumulative impacts to snags in green forest habitat. As a result, existing snags in green forest habitat conditions and hairy woodpecker habitat conditions would be maintained.

Cumulative Effects Conclusion

It is anticipated that implementation of the No Action Alternative, in combination with present and reasonably foreseeable future actions, would not have a cumulative effect to the population and habitat distribution across the Plumas National Forest. Thus, existing snags in green forest habitat conditions and hairy woodpecker habitat conditions would be maintained.

Effects of the Action Alternatives

Direct and Indirect Effects to Habitat

Changes under each action alternative would be very nominal. The potential exists for some snags to be removed due to safety and operability concerns; however, snag recruitment is also expected with retention of 30”+dbh conifers and some recruitment due to fire kill. The net result of snag loss and gain is undetermined. However, the two action alternatives call for the retention of snags at SNFPA Standards (3 to 6 snags/acres, ≥15” dbh), where available. Since the pine types are currently below standards, it would be important to leave all snags >12” dbh in the pine types.

Cumulative Effects Conclusion

It is anticipated that implementation of the action alternatives, in combination with present and reasonably foreseeable future actions would decrease the amount of snags in green forest habitat within the Wildlife Analysis Area. These changes will not alter the existing trend in the snags in green forest habitat.

Relationship of Project-Level Habitat Impacts to Bioregional-Scale Hairy Woodpecker Trend

The direct/indirect and cumulative effects of the Ingalls Project, in terms of potential medium-sized and large-sized snags per acre within green forest habitat, under action alternatives would not change with time, the amount and distribution of snags in green forest habitat within the Wildlife Analysis Area. Since there will be no affect, the Ingalls Project will not alter the existing trend in the ecosystem component, nor will it lead to a change in the distribution of hairy woodpecker across the Sierra Nevada bioregion.

Water and Soil Resource Effects Assessment

Introduction

This assessment addresses impacts to both hydrologic resources and soil resources. Cumulative watershed effects (CWE) analyses have traditionally focused on impacts to downstream beneficial uses. These include aquatic habitat, hydroelectric power generation, and domestic water supplies. Information has come to light that places considerable emphasis on near-stream disturbances and their site-specific biological effects as well as the downstream physical effects (Menning et al. 1996, McGurk and Fong 1995). This CWE analysis addresses effects to both near-stream and downstream uses by using the Region 5 Cumulative Off-site Watershed Effects Analysis method (USDA Forest Service 1988a). This method is based on the concept of equivalent roaded acres (ERA), which is described in the Cumulative Watershed Effects Method section of this document.

Soils provide the nutrient and hydrologic foundation necessary to sustain terrestrial ecosystems. Soil productivity is generally considered the capacity of soils to produce plants. Indicators of soil productivity include soil cover, soil porosity, and organic matter. Maintenance of soil cover is important to prevent accelerated soil erosion. Soil porosity is used to assess soil compaction. Organic matter in the soil and on the soil surface stores nutrients used by plants and organisms that inhabit the soil. Threshold values indicate when changes in soil properties and soil conditions may result in long-term losses in inherent productivity or hydrologic function of the soil. Detrimental soil disturbance may result when threshold values are exceeded for certain soil properties.

Effects Analysis Methodology

Scope of the Analysis

This section describes the geographic and temporal boundaries utilized in this assessment. These areas differ for the watershed effects analysis and the soil assessment areas.

Table 38. Summary of Environmental Indicators and Measures Examined in this Assessment

Key Ecosystem Element	Environmental indicators	Variable Assessed
Water Quality	Chronic Sedimentation	Equivalent Roaded Acres
Soil Productivity	Organic Matter losses Large Woody Debris losses Soil loss Reduced Vegetation Establishment and Water Infiltration	Surface Fine Organic Matter Large Woody Debris Effective Soil Cover Detrimental Compaction

The geographic area examined for the cumulative watershed effects analysis consists of the 16 subwatersheds that have treatments proposed within their boundaries. These subwatersheds encompass approximately 16,464 acres, or about 4 percent of the Beckwourth Ranger District.

These analysis subwatersheds range from 363 to 2,976 acres in size. Five of the subwatersheds (Big Grizzly, Old House, Lightning, Vulture, and Sullivan) are in the Freeman Creek Hydrologic Unit Code 6 (HUC6) watershed, and 11 subwatersheds (Light, Crystal, Coldwater, Turner, Red, Contact, Wilson, Ridge, Bagley, Pebble, and Marble) are in the Lower Red Clover Creek HUC6 watershed (Figure 10). The Freeman Creek HUC6 watershed is part of the Lake Davis HUC5 watershed. The Lake Davis HUC5 watersheds drain into the Middle Fork of the Feather River. The Lower Red Clover Creek HUC6 Watershed is part of the Red Clover Creek HUC5 watershed. The Red Clover Creek HUC5 drains into Indian Creek, which drains into the East Branch of the North Fork of the Feather River.

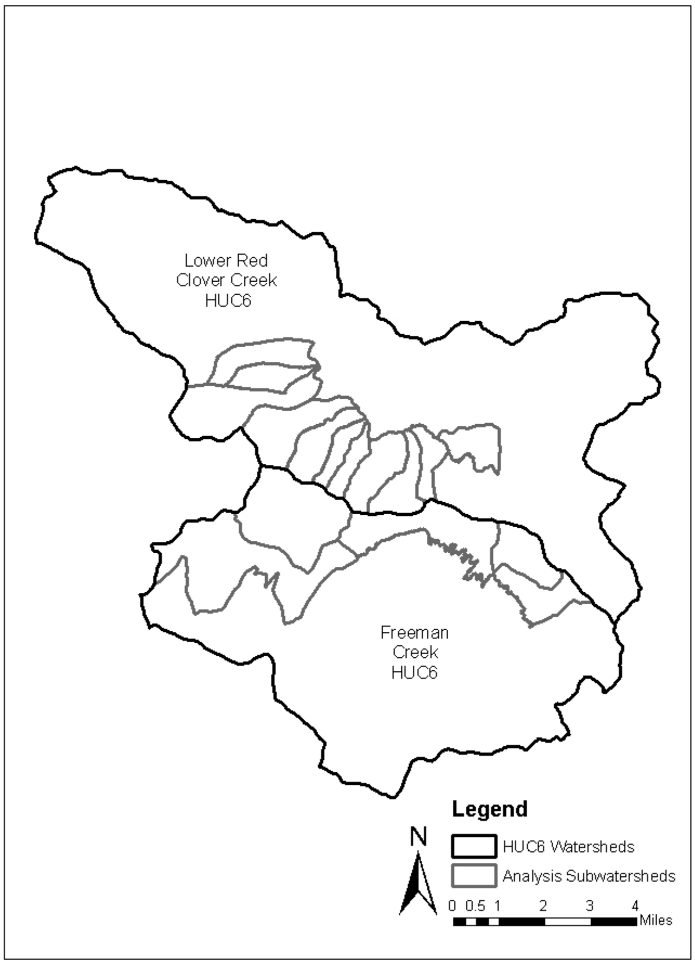

Figure 10. The two HUC6 watersheds that encompass the Ingalls Project area.

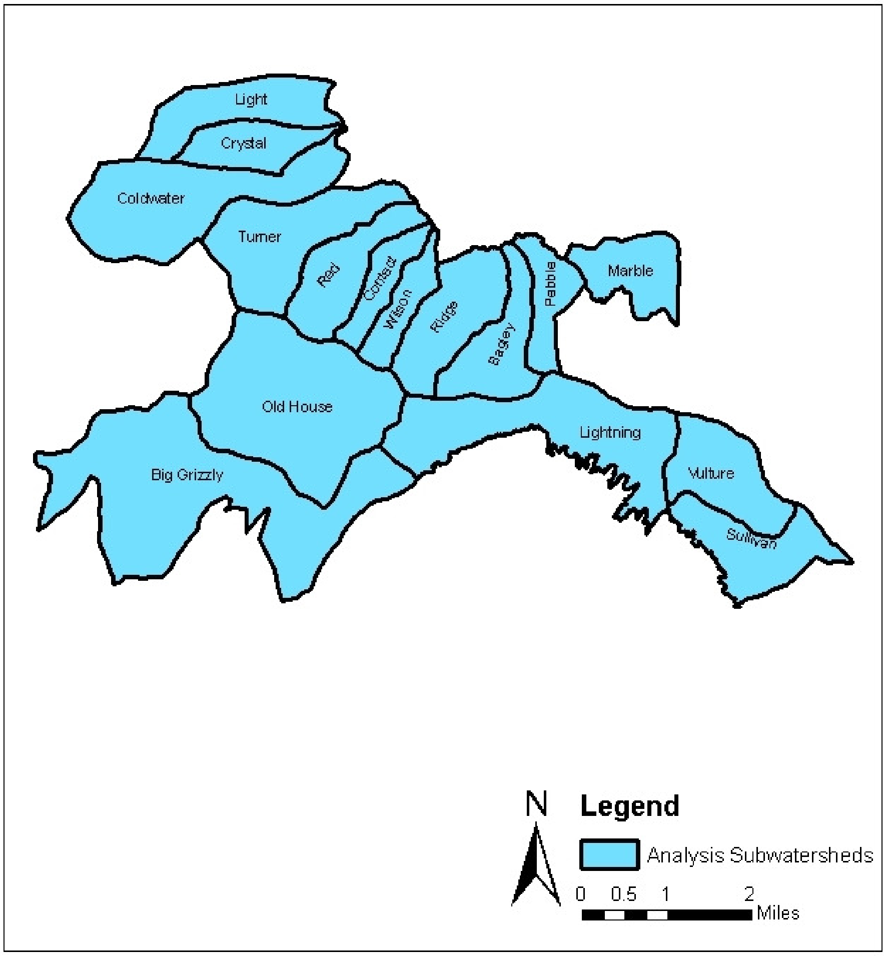

Figure 11. The analysis subwatersheds examined for cumulative watershed effects.

The temporal bounds of the watershed effects analysis typically range from 25 to 35 years. However, this value varies depending on the type of disturbance activity contributing to cumulative effects. Timber harvest activities were generally considered recovered after 30 years, so harvests occurring prior to 1981 were excluded from the effects model. For variables that do not recover within 30 years (e.g. soil compaction) accommodations are made within the analysis. Wildfire effects were considered recovered after 10 years. No temporal component was included for existing roads, regardless of when they were constructed. This assumes that the existing roads get enough use and/or maintenance to maintain them in their current state. The timeframes chosen to analyze the effects of anthropogenic and natural disturbances to watersheds reflect the resultant recovery of changes to watershed function, specifically surface runoff patterns and timing.

In addition, the mechanical and underburn treatment units (2,630 – 3,324 acres) which are part of the proposed treatment area (4095 acres) within the project area (17,909 acres) were used as the geographical area examined for the soil assessment. The temporal bounds of the soil assessment range from 10 to 30 years because climate change, unforeseeable future projects, demographic changes, etc… make assumptions beyond this period speculative.

Cumulative Watershed Effects Methodology

For the purpose of this CWE analysis, the effects of past, present, and reasonably foreseeable future impacts were assessed using the Region 5 Cumulative Off-site Watershed Effects Analysis (USDA Forest Service 1988a).

Defined beneficial uses for project watersheds are described below and include water recreation, industrial, municipal, terrestrial wildlife habitat, and cold freshwater habitat. Among these beneficial uses, aquatic habitat is the most sensitive to adverse sedimentation and water temperature or chemistry effects that could potentially result from land disturbing activities such as those proposed for this project. Alterations to watershed hydrology are believed to be the most probable mechanism for initiating these effects on aquatic habitat (USDA Forest Service 1988a). The Region 5 CWE model utilizes conceptual site disturbance coefficients called equivalent roaded acres (ERA) to track changes in the hydrologic functioning of watersheds. ERA coefficients are used to compare the effect of management activities such as timber harvest, pile burning, underburning, and grazing to the effect of a road in terms of altering surface runoff patterns and timing. Disturbances are added together to determine a cumulative ERA value for each analyzed watershed. Dividing the total ERA by the size of the watershed yields the percent of the watershed in a hypothetically roaded condition.

Watersheds and their associated stream systems can absorb some level of land disturbance without causing unacceptable effects to beneficial uses of water. However, there is a point where additive or synergistic effects of land use activities would cause a watershed to become highly susceptible to cumulative effects. For the Region 5 model, the estimated upper limit of watershed tolerance is called the threshold of concern (TOC). For this analysis, when the total calculated ERA in a watershed, expressed as a percentage of the watershed area, exceeds the TOC, susceptibility for adverse cumulative effects to downstream beneficial uses is high.

The R5 Soil and Water Conservation Handbook (USDA Forest Service 1988a) states that the TOC does not represent the exact point at which cumulative watershed effects will occur. Rather, it serves as a “yellow flag” indicator of increasing susceptibility for significant adverse cumulative effects occurring within a watershed. Susceptibility to negative impacts are increased as a watershed approaches or is impacted beyond the TOC. If the watershed is approaching or above the TOC, a more thorough investigation of the activities planned within the watershed is necessary. Additional field surveys and/or more detailed analysis are done for subwatersheds that approach or exceed TOC or experience considerable increases in ERA.

Project level TOCs are estimated by considering the sensitivity of each analyzed watershed. Natural watershed sensitivity is an estimate of a watershed's natural ability to absorb land use impacts without increasing the effects of cumulative impacts to unacceptably high levels (USDA Forest Service 1988a). Measures used to evaluate watershed sensitivity include the potential for: 1) soil erosion; 2) high intensity and/or long duration precipitation events, including rain-on-snow; 3) landslides and debris flows; and 4) channel erosion within alluvial stream channels. The TOC generally ranges between 12 percent and 20 percent ERA depending upon the intrinsic sensitivity of the watershed and beneficial uses of water (USDA Forest Service 1988a). Based upon the assessment of these measures within the Ingalls analysis subwatersheds, as well as a review of land use history and resultant impacts to beneficial uses in similar watersheds, the TOC has been conservatively set at 12 percent ERA for the upland areas of each analyzed subwatershed.

In recent years, ERA analyses have focused more attention on near stream activities with respect to sediment yields and peak flows. It has been shown throughout the literature over the past century that most sediment delivery originates within close proximity to stream courses, whether they are perennial, intermittent, or ephemeral streams. For this analysis, ERA values for each watershed are calculated and reported separately for near-stream areas and upland areas. The TOC for sensitive areas has been conservatively set at 8 percent ERA.

For this project analysis, the indicated risk of CWE is a conservative estimate because, in most cases, the reported ERA values within sensitive areas are over-predicted due to how the timber activity was entered into the GIS interface. In most cases sensitive areas and their corresponding protection buffers that were not treated as part of timber activity have not been excluded from the treated area GIS layer. Therefore, the ERA values within the sensitive areas for the analyzed subwatersheds end up being an over prediction of the actual disturbance that has occurred within these areas. Additionally, acres within internal exclusion zones (no proposed treatment) and 25 percent or greater slope restriction zones within the RHCAs and SMZs were not omitted as part of this analysis.

Over the years since the R5 CWE model was developed, Plumas National Forest watershed staff have developed ERA disturbance coefficients based on visual observations, field surveys, published studies, transects, and aerial photo interpretation. Coefficients vary by past management activity, silvicultural prescription, site preparation methods, type of equipment utilized, and wildfire severity.

Disturbances were calculated with Geographic Information System (GIS) programs, using Plumas National Forest modified corporate data files. While substantial efforts are made to keep revising these data files as new information becomes available, site-specific field verification is required to more accurately capture attributes within the analysis area. Roads and stream channels are the emphases of this verification based upon findings from past management activities that showed that there may be up to 20% more roads on the landscape than are depicted in the corporate data. Conversely, the corporate data tends to over predict the presence of ephemeral streams, and occasionally fails to predict the presence of some stream segments. Where treatment activities are proposed, field data was collected to verify the presence or absence of stream courses and additional roads within the treatment units. These field-verified files were used when calculating ERA contributions. Stream miles, road densities, and road-stream crossing information presented are based on a combination of corporate data files and field verified data.

The assessment of past fire events was restricted to events within the last 10 years based on visual observations, field surveys, published studies, and aerial photo interpretation. Beyond this time frame, vegetation has generally had ample opportunity to reestablish and develop adequate crown cover to provide organic material to the soil; thereby providing physical protection against soil erosion, which decreases adverse effects on channel condition, fisheries, and water quality. According to the fire history on the Plumas National Forest there were no large fires that occurred within the analysis area within the last 10 years, and therefore no wildfires were included in this analysis.

The assessment of past timber harvest activities was restricted to events within the last 30 years. This value reflects the period of time required for site recovery following these types of activities and events. Beyond this period, vegetation has generally had ample opportunity to reestablish and develop adequate crown cover to provide organic material to the soil. Together, crown and litter cover provide physical protection against soil erosion. In addition, roots have reoccupied the soil mantle and most effects from compaction have been negated except along established roadways and some skid trails, temporary roads, and landings. These factors tend to moderate peak flows, and therefore diminish adverse effects on channel condition and water quality. A linear recovery coefficient was incorporated into the analysis to reduce the disturbance coefficients over a 30-year period.

Soil Assessment Methodology

Soil quality standards and guidelines that apply to this project exist at the Forest level with the Plumas National Forest Land and Resource Management Plan (USDA Forest Service 1988) and at the bioregional level with the Sierra Nevada Forest Plan Amendment Record of Decision (USFS PSW, 2004b). These standards and guidelines focus on protection and improvement of National Forest System lands for continuous forest and rangeland productivity and favorable water flows. To address these standards and guidelines, this soil assessment focused on soil productivity measures including surface organic matter, soil cover, compacted soils, and large woody debris. Ten to thirty years was chosen as a temporal timeframe for soil effects. After this time, the degree and variability of soil disturbances are expected to be similar to the No Action Alternative.

A field crew assessed soil productivity measures across 69 percent of the acreage that has been proposed for mechanical and/or prescribed fire treatment. The surveys were completed during the summer of 2010. Within the areas that were to be sampled, transects were randomly selected. To prevent locating transects parallel to skid trails, and thereby inadequately sampling them, transects were intentionally located so as to not run directly up and down a slope. In addition, transects were placed between system roads in order to concentrate sampling in the ground disturbing activity areas. Transects had 40 to 50 sample points. Transect length often varied and two transects were covered in each unit sampled. Transects were placed between the roads according to the slope conditions described above when a sampling area was bound by two system roads. Sample points were evenly distributed along the transect. At each point, the type of ground cover, detrimental compaction, and presence of skid trails and landings were determined.

Cover categories included three depth classes of duff and litter, three size classes of woody debris, live vegetation, rock, or bare soil. If bare soil was encountered, an assessment was made to categorize the location as disturbed or undisturbed by management activities, showing evidence of erosion or deposition, or recently burned.

For the purposes of this analysis, it was assumed that a 10 percent reduction in total soil porosity corresponds to a threshold soil bulk density that indicates detrimental soil compaction. To assess for detrimental soil compaction, the "spade method" was used which consists of measuring compaction from the resistance felt from sticking a spade shovel into the ground at the transect sample point. Soil bulk density samples were collected and analyzed on soils found in the project area to calibrate the spade method and assure that the person performing the test properly correlated the resistance felt with threshold soil bulk densities. Subsequently, a 12-16'' deep and 6-12'' wide hole was excavated with the spade to assess whether detrimental compaction exists based upon field indicators of soil compaction.

Affected Environment/Environmental Consequences

Affected Environment

The Ingalls project is located on the Beckwourth Ranger District of the Plumas National Forest (PNF) within the Sierra Nevada Mountain Province. The project area is within the Mt. Ingalls (#31), Lake Davis (#37), and Dotta (#36) Management Areas identified in the PNF Land and Resource Management Plan.

Precipitation

Average annual precipitation in the project area is approximately 34-45 inches. Variations in precipitation accumulation are dependent upon topography, with the higher elevations receiving more than the lower elevations. Elevations within the project area range from 5,160 feet to 8,372 feet. Precipitation falls primarily as snow above 6,000 feet, with yearly snowfall total approaching 62 inches at 6,900 feet. Snow estimates are a 10 year average from the Grizzly snow course (Department of Water Resources California Data Exchange Center). Precipitation distribution is characteristic of the Mediterranean climate, with most precipitation occurring between October and May. About half of the annual precipitation falls during December, January, and February. Surface runoff depends upon the snowmelt regime, which normally extends into late spring and early summer.

Soils and Parent Materials

The geology of the analysis area is primarily composed of Tertiary andesite, Tertiary rhyolite, Tertiary basalt, and Quaternary lake deposits. The various Tertiary geologic types dominate the analysis area and are found throughout the steeper terrain on the north and south sides of Turner Ridge. The Quaternary lake deposits are found in the flatter terrain in Grizzly Valley and along the north side of Lake Davis. Generally soils that are derived from extrusive igneous parent materials, including those found within the project area, have an affinity for mass instability, compaction, and road maintenance problems.

Soils throughout the project area vary considerably, with the occurrence of over 17 individual soil types. The maximum erosion hazard ratings of the soil types that are in the areas proposed for project activity range from low to high (**Error! Reference source not found.**). The texture classes of these soils range from clay loam to loamy sand. Barren rocky outcroppings occur occasionally throughout the project area. Stream flow is highly responsive to rainfall and snowmelt events once the soils become saturated. Stream channels will also respond when precipitation rates exceed the rate of infiltration (i.e. during a thunderstorm event). In this case, substantial surface runoff may occur.

Stream Channels and other Sensitive Areas

There are approximately 175 miles of stream channels in the analysis watersheds according to PNF corporate GIS files and project area stream survey data. These channels are made up of a variety of stream types with approximately 28 miles of perennial streams, 24 miles of intermittent streams, and 123 miles of ephemeral streams. Stream channels on the southern half of the project area are tributaries to Lake Davis, while stream channels on the northern half of the project area tributaries to Red Clover Creek. The stream channels within the proposed treatment units were surveyed to verify flow regimes and subsequent Riparian Habitat Conservation Area (RHCA) and Streamside Management Zone (SMZ) buffer designation. Buffer zone widths will vary from 50 to 300 feet depending on channel characteristics, flow regime, and the presence of fish (see SOPs in Appendix B).

Forty-nine springs, seeps, and wetlands were located in the analysis watersheds through a combination of field surveys by District Watershed Staff, District Botanists and corporate GIS database research. Forty-eight of these features are less than one acre in size, while one is greater than an acre. Buffer zone widths will vary from 100 to 150 feet around seeps, springs, and wetlands that are less than one acre and greater than one acre, respectfully. For the purposes of the ERA model, these buffered areas were incorporated into the “sensitive areas” GIS layer along with buffered RHCAs and SMZs.

These areas will be protected in a manner consistent with the Riparian Management Objectives (HFQLG FEIS), Riparian Habitat Conservation Area and Streamside Management Zone Plan and the Standard Operating Procedures (SOPs) for RHCAs and SMZs that can be found in the Appendix B of the Ingalls Project EA.

Beneficial Uses

Existing beneficial uses for the surface waters of the Ingalls Project area are identified in the Central Valley Water Quality Control Plan for the Sacramento and San Joaquin River Basins (California Regional Water Quality Control Board 2007). This plan identifies beneficial uses for specific water bodies and states that those beneficial uses generally apply to tributary systems of those water bodies. The 11 subwatersheds that are located north of Turner Ridge are tributaries to the North Fork of the Feather River. Existing beneficial uses for the North Fork of the Feather River include, municipal, industrial, recreation, and fish and wildlife habitats as defined below.

Municipal

Municipal and Domestic Supply – Uses of water for community, military, or individual water supply systems including, but not limited to, drinking water supply.

Industrial

Hydropower Generation – Uses of water for hydropower generation.

Recreation

Water contact recreation – Uses of water for recreational activities involving body contact with water, where ingestion of water is reasonably possible. These uses include, but are not limited to wading and fishing.

Non-contact water recreation – Uses of water for recreational activities near water, but where there is generally no body contact with water, nor any likelihood of ingestion of water. These uses include, but are not limited to, picnicking, sunbathing, hiking, camping, marine life study, hunting, sightseeing, or aesthetic enjoyment in conjunction with the above activities.

Fresh Water Habitat & Spawning, Reproduction, and/or Early Development

Cold freshwater habitat – Uses of water that support coldwater ecosystems including, but not limited to, preservation or enhancement of aquatic habitats, vegetation, fish, or wildlife, including invertebrates. Uses of water that support high quality aquatic habitats suitable for reproduction and early development of fish.

Wildlife Habitat

Uses of water that support terrestrial or wetland ecosystems including, but not limited to, preservation and enhancement of terrestrial habitats or wetlands, vegetation, wildlife (e.g., mammals, birds, reptiles, amphibians, invertebrates), or wildlife water and food sources.

The five subwatersheds in the assessment area that are located south of Turner Ridge are tributaries to Lake Davis. Existing beneficial uses for Lake Davis include, recreation and fish and wildlife habitats as defined below.

Recreation

Water contact recreation – Uses of water for recreational activities involving body contact with water, where ingestion of water is reasonably possible. These uses include, but are not limited to wading and fishing.

Non-contact water recreation – Uses of water for recreational activities near water, but where there is generally no body contact with water, nor any likelihood of ingestion of water. These uses include, but are not limited to, picnicking, sunbathing, hiking, camping, marine life study, hunting, sightseeing or aesthetic enjoyment in conjunction with the above activities.

Fresh Water Habitat & Spawning, Reproduction, and/or Early Development

Cold freshwater habitat – Uses of water that support coldwater ecosystems including, but not limited to, preservation or enhancement of aquatic habitats, vegetation, fish, or wildlife, including invertebrates. Uses of water that support high quality aquatic habitats suitable for reproduction and early development of fish.

Warm freshwater habitat – Uses of water that support warm water ecosystems including, but not limited to, preservation or enhancement of aquatic habitats, vegetation, fish, or wildlife, including invertebrates.

Wildlife Habitat

Uses of water that support terrestrial or wetland ecosystems including, but not limited to, preservation and enhancement of terrestrial habitats or wetlands, vegetation, wildlife (e.g., mammals, birds, reptiles, amphibians, invertebrates), or wildlife water and food sources.

Environmental Consequences

Alternative 2 – No Action (Water Resource Indicators)

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen, and Cottonwood Treatments

Measurement Indicator 1 – Measurement Indicator 1 – Acres of DFPZ and Area Thin fuels reduction, aspen and cottonwood treatments within sensitive (i.e. RHCAs and SMZs) and upland areas.

Under the No Action Alternative, on site and downstream water quality and impacts to beneficial uses (e.g. drinking water, swimming, hydro power, etc.) of surface waters would remain unchanged in the immediate future. The No Action Alternative will maintain the existing condition of the water resources, riparian environment, and stream channels. Stabilization of stream channels and treatment of heavy concentrations of fuels that would reduce fire hazard and decrease the potential for large fires within the sensitive and upland areas and subsequent effects to water quality would not occur under this alternative. Subwatersheds will continue to regain their inherent hydrologic character as stand growth continues and previously disturbed sites recover. Given this site recovery, sections of streams within these subwatersheds that are in poor to fair condition would experience a very gradual, long-term improvement in channel stability as peak flows and sedimentation rates decrease. Sedimentation from roads would continue since a number of the roadways are in poor condition and situated in close proximity to streams.

This description assumes that fires are controlled to spot locations over the next 20 to 30 years. Given the increase in fuel loading resulting from insect mortality, there is a reasonable probability that a large, intense wildfire would occur during this time frame. It can be expected that this type of fire would be intense; destroying vegetation, ground cover and large organic debris within stream channels. A large intense fire within these drainages could cause peak flows to increase five to ten times above existing levels and sediment loads could increase up to 50 to

100 fold. On-site fishery habitat may be destroyed or severely reduced since a large fire could cause the stream to become devoid of cover, large organic debris, and aquatic food.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects. (Alternative 2)

Measurement Indicator 2 – Road density (miles per square mile) within the analysis subwatersheds.

Road densities are used as a risk assessment to assess direct and indirect effects of roads within the analysis subwatersheds. Hence, the mileage of roads per watershed in units of mile of road per square mile of land is an important tool for providing a risk rating of effects within RHCAs and SMZs and uplands. Roads and trails near streams are more likely to have an effect on stream function than those outside of RHCAs and SMZs (i.e. upland areas), due to their proximity to streams. Table 39 displays existing road densities and stream crossings within the analysis subwatersheds. Roads included in this analysis are system (County, and Forest-Service), and non-system (unclosed temporary access roads and undesignated OHV routes) roads.

Many of the analysis subwatersheds have an existing condition of moderate to high road densities and stream crossings. Road density in the analysis subwatersheds ranges from 1.9 to 5.3 miles of road per square mile of watershed area.

Table 39. Subwatershed Characteristics and Road Miles and Densities for Alternative 2.

Analysis subwatershed	Subwatershed Area (mi^2)	Miles of Stream by Type			Number of Road-Stream Crossings	Miles of Road	Road Density (mi/mi^2)
		Perennial	Intermittent	Ephemeral			
Light	1.2	0.6	1.6	4.7	21	6.4	5.3
Crystal	0.8	1.7	0.1	4.2	14	3.0	3.8
Coldwater	2.4	2.9	0.3	13.9	58	10.2	4.3
Turner	1.8	2.0	1.1	10.0	30	7.6	4.2
Red	1.1	1.2	1.2	5.7	15	3.4	3.1
Contact	0.6	1.0	0.9	3.5	10	1.4	2.3
Wilson	0.6	1.1	0.4	3.9	10	2.1	3.5
Marble	0.9	2.0	0.5	4.7	12	1.7	1.9
Pebble	0.7	1.1	0.1	3.4	8	1.3	1.9
Bagley	1.1	0.0	2.6	4.5	17	5.2	4.7
Ridge	1.3	2.4	1.2	8.0	14	4.4	3.4
Old House	3.5	3.1	4.6	12.9	53	13.7	3.9
Lightning	2.7	0.1	1.5	16.0	32	10.2	3.8
Big Grizzly	4.7	8.3	4.0	18.9	67	17.1	3.6
Vulture	1.2	0.0	2.5	3.1	12	3.6	3.0
Sullivan	1.2	0.1	1.2	5.5	23	4.7	3.9

Road-stream crossings range from 8 to 67 crossings per subwatershed. Road-stream crossings are of particular importance due to the fact that they often have a direct effect of contributing substantial amounts of sediment to stream channels (Gucinski et al. 2001) and potential sites for stream capture by the road. Flow capture by roads and trails that results in erosion of the road prism can result in indirect effects to stream channels in the form of excessive sedimentation. All crossings of perennial streams by unauthorized roads are assumed to be sources of sediment to streams. Crossings for unauthorized roads/routes are assumed to be unimproved fords, as they are not maintained to standards. On the other hand, Best Management Practices (BMPs) have been installed on a majority of roads and trails to reduce erosion and sedimentation at crossings and to prevent stream capture.

Under the No Action Alternative, the project activities to improve forest access and reduce transportation impacts would not occur. Direct and indirect impacts of high road densities and stream crossings would remain unchanged within the analysis subwatersheds.

Cumulative Watershed Effects Analysis – Water (Alternative 2)

Measurement Indicator 3–Equivalent Roaded Acres (ERA) values within analysis subwatersheds

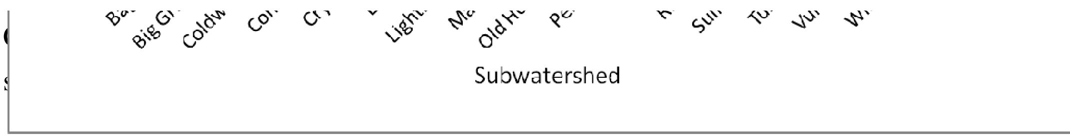

Figure 13 present a graphical representation of the major land uses that have contributed to the existing ERA values in each subwatershed. The ERA values vary across the subwatersheds due in part to road densities, past management activities, current livestock grazing, and current fuels management projects.

The Big Grizzly subwatershed has an upland ERA value that exceeds the determined TOC (12 percent ERA) and therefore is at a higher risk of generating offsite cumulative watershed effects. Factors leading to the high ERA value include past and current timber and fuels reduction activities, existing road densities, and livestock grazing within the subwatershed. It is important to note that nearly half of the upland ERA value is comprised of very recent or current DFPZ fuels reduction that have been or will be implemented under the Grizz and Freeman Projects, which were designed in part to reduce the likelihood of catastrophic wildfire. ERA totals that exceed the TOC indicate that natural watershed hydrology may be significantly altered, particularly with respect to alterations of surface runoff patterns and timing. Such alterations can result in scour and degradation of adjacent stream channels and/or increased hillslope erosion over natural rates with potential delivery of fine sediment to streams. However, based upon stream and soil surveys along with several site visits, many of the sensitive areas in the Big Grizzly subwatershed have not been impacted to degree that has been suggested by the ERA model.

ERA values for the sensitive areas of the Big Grizzly, Lightning, Old House, and Vulture, subwatersheds exceed the determined TOC (8 percent ERA) and therefore are at a higher risk of generating offsite cumulative watershed effects. Similar to the upland areas, the modeled ERA values are the result of timber harvests, fuels reduction projects, roads, and livestock grazing. However, the observed existing condition of stream channels and adjacent riparian buffers indicate that these subwatersheds have not been impacted to degree that has been suggested by the ERA model. Off-site cumulative watershed effects have not resulted in an impairment of the receiving water bodies or a failure of these waterbodies to provide their established beneficial uses.

Under the No Action Alternative, ERA values in the analysis subwatersheds would remain unchanged. Assuming that disturbances other than those listed in the *Present and Future Foreseeable Activities* section of this document do not occur, the modeled effects of past land disturbances would eventually return to pretreatment condition. Under this condition, the only ERA values that would be maintained would be the values from the roads and livestock grazing.

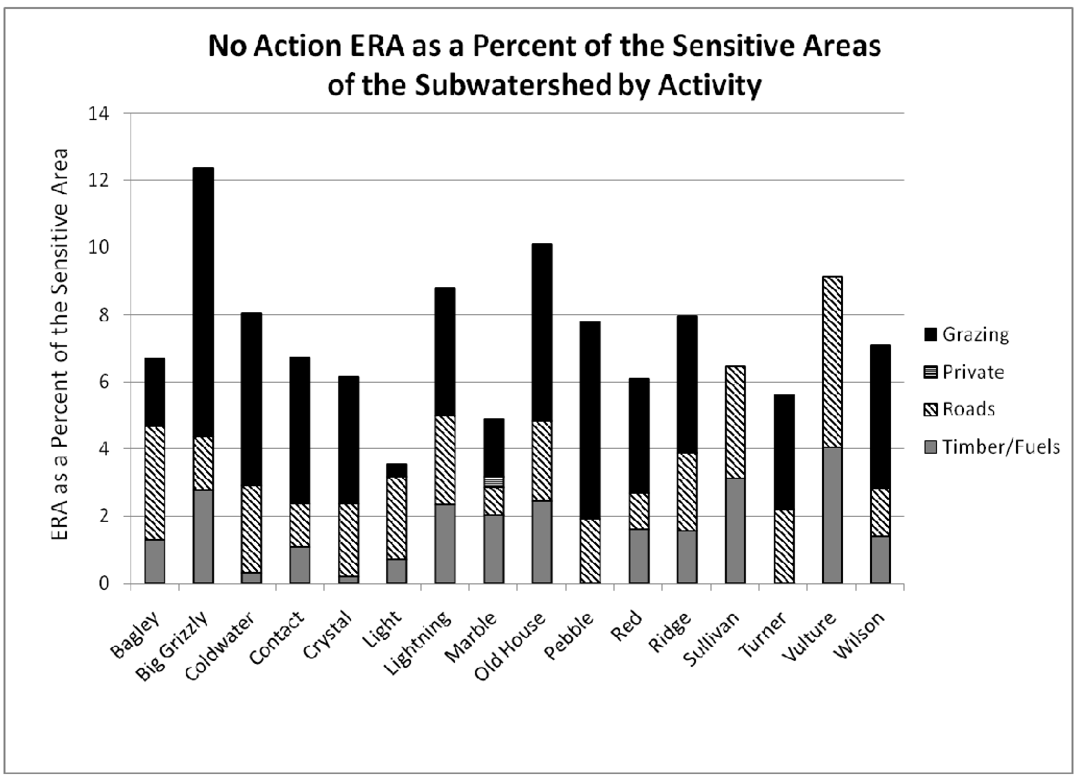

Figure 12. Alternative 2, the existing condition: Equivalent roaded acres (ERA), shown as a percent of the sensitive areas within each analysis subwatershed.

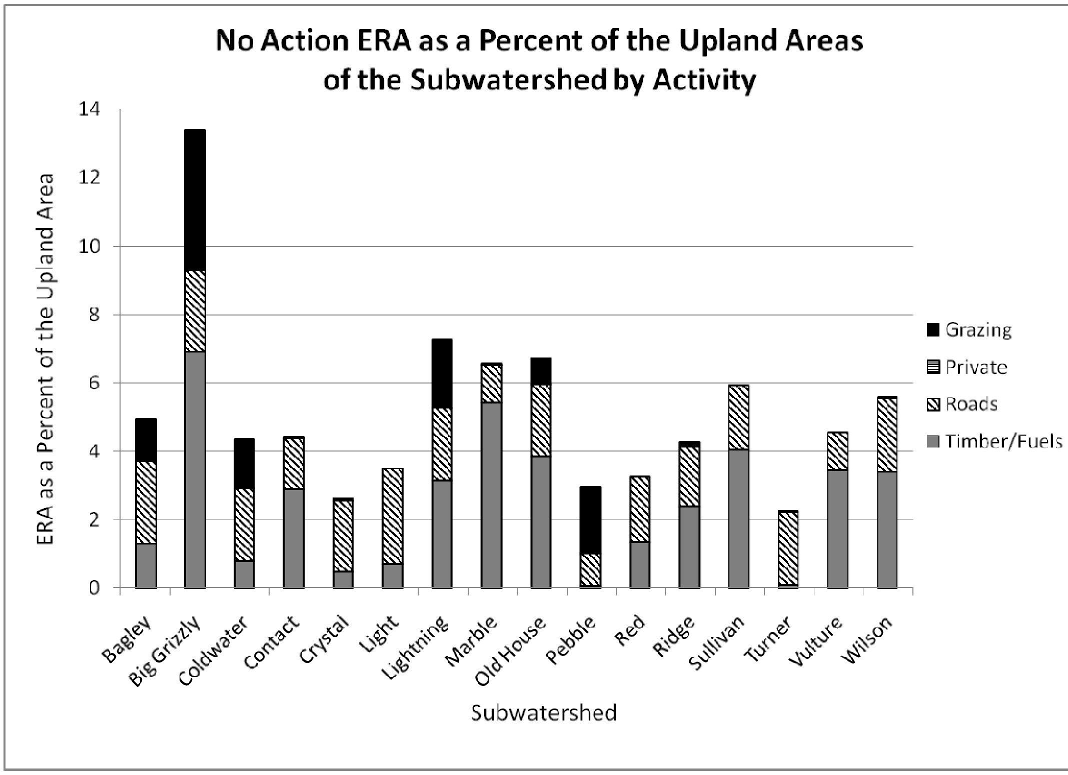

Figure 13. Alternative 2, the existing condition: Equivalent roaded acres (ERA), shown as a percent of the upland areas within each analysis subwatershed.

Soil Resource Indicators (Alternative 2)

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen and Cottonwood Treatments (Alternative 2)

Measurement Indicator 4 –Soil productivity (soil ground cover, fine organic matter and large woody material, soil porosity/compaction and soil buffing capacity) changes within DFPZ and Area Thin fuels reduction, Aspen and Cottonwood treatment units

Soil Cover

Under the No Action Alternative, soil cover will continue to increase as a result of needle cast and other material falling from trees. This accumulation of material was observed in units surveyed in 2010. The continued establishment of grass and shrub species will also provide additional soil cover. As a result of increased soil cover, the risk of soil erosion will decline on forested hillslopes. Soil cover dissipates the energy of falling raindrops through interception. Without soil cover, falling rain causes rain splash, a force that loosens soil and sets soil grains in motion. The litter layer acts as a sponge by increasing storage capacity and slowing the velocity of overland flow. At high velocities overland flow results in rain-wash, another erosive force. Without vegetative cover, an intense storm can generate huge quantities of sediment from hillsides (Cawley 1990). Reduced soil erosion helps retain soil nutrients and a favorable growth medium on site.

Organic Matter and Large Woody Debris

Surface organic matter and large woody debris (LWD) serve as a nutrient reservoir for plants and other organisms that inhabit the soil. As they are incorporated into the soil through decomposition, surface organic matter and LWD contribute positively to water-holding capacity, nutrient retention, infiltration, and hydrologic function of the soil. Surface organic matter acts as a buffer to moderate extremes of soil temperature.

Under the No Action Alternative, surface organic matter can be expected to increase as organic materials continue to accumulate. LWD amounts can also be expected to increase as trees fall to the forest floor in the coming years. An increase in organic matter and LWD would result in improvements to the water-holding capacity, nutrient retention, infiltration, and hydrologic function of the soil. However, the continued accumulation of organic matter and LWD on the forest floor would contribute to increased ground and surface fuel loads, which may lead to increased fire severity and intensity during a fire event.

Soil Porosity and Detrimental Compaction

Field assessments completed for soil compaction, skid trails, and landings were conducted on proposed mechanical treatment units. Compaction values ranged from 0 to 34 percent of the points surveyed in each unit, while skid trail and landing presence ranged from 0 to 22 percent of the points surveyed.

Under the No Action Alternative, the extent and degree of compaction are expected to decline slowly over time. This process may take several decades in forested environments (Grigal 2000). Root penetration, extension, and decay, along with the burrowing action of soil dwelling animals, would contribute to the increase in soil porosity and decrease in compaction. In addition, incorporation of organic matter into the soil by biological processes such as invertebrate and vertebrate soil mixing, and decomposition, would help reduce soil bulk density and the degree of compaction in affected areas over time.

The No Action Alternative will maintain the existing condition of soil ground cover, organic matter, large woody debris, soil porosity, and detrimental compaction. Activities to improve soil productivity elements in areas that do not currently meet the desired conditions would not occur with this alternative.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects. (Alternative 2)

Measurement Indicator 5 –Miles of road maintenance, reconstruction, obliteration and temporary road construction within analysis subwatersheds.

Currently there are approximately 96 miles of roads throughout the analysis subwatersheds. Under this alternative, it is assumed that most roads within the analysis subwatersheds would continue to exist and be maintained at their current levels. Therefore, most roads would continue to exhibit denuded and highly compacted soil, thereby having direct and indirect effects to soil productivity throughout the analysis subwatersheds. However, some roads may become revegetated as limited use occurs on them, which may increase porosity and ground cover gradually over time as the road naturally recovers. Restoration and improvement of road conditions would not occur. However, short-term detrimental soil productivity effects associated with temporary road construction also would not occur with this alternative.

Cumulative Watershed Effects Analysis – Soils (Alternative 2)

Soil Cover

Under the No Action Alternative, it is assumed that soil productivity elements would continue to improve. Ground cover can be expected to increase as organic materials accumulate on the soil surface. However, given the amount of standing surface and ladder fuels in some of the units surveyed within the analysis area, there is a high potential for recruitment of hazardous levels of fuels. The current fuel conditions within the Ingalls project consist of moderate to high amounts of surface, ladder and canopy fuels. This accumulation of fuels could result in a high severity wildfire within the analysis area, which in turn would likely consume organic materials on the forest floor and reduce soil cover in the affected area. If soil cover were reduced to bare soil over a widespread, contiguous area following a wildfire, the soil would be much more susceptible to erosion.

In addition, fire can volatilize organic compounds in the soil, some of which migrate down a temperature gradient and condense on soil particles below the surface (DeBano 1990). As a result, hydrophobicity (a non-wettable layer) can develop below the surface. This repellant layer can greatly reduce infiltration rates. During a precipitation event, soil above the non-wettable layer can become saturated and erode downslope due to rill formation and raindrop splash. Factors such as soil texture, slope, and post-burn precipitation intensity will affect the degree and type of post-fire erosion. Dry, coarse grained soils are particularly susceptible to this type of fire-induced hydrophobic condition (Clark 1994).

Organic Matter and Large Woody Debris

Under the No Action Alternative, surface organic matter can be expected to increase as organic materials continue to accumulate. However, a future wildfire could consume organic horizons on the forest floor, creating a non-wettable layer, as described above. Immediately following a high-intensity wildfire, organic matter levels would be reduced significantly due to consumption of finer materials on the forest floor. However, depending on the fire intensity, within several months a thin layer of needlecast from scorched trees would increase cover of organic matter (Pannkuk and Robichaud 2003). Fires short-circuit the decomposition pathway, rapidly oxidizing organic matter and releasing available nutrients to plants and soil organisms. When organic matter burns, essential nutrients can be transferred to the atmosphere through volatilization and ash convection (Raison 1985). Nutrients may also be lost following fire due to leaching (Boerner 1982). Some nutrients are returned relatively quickly by terrestrial cycling pathways. Compared to the pre-burn condition, a large reduction in the organic matter covering the soil would reduce the insulating effect this layer has on soil temperature. Under a reduced organic layer, soils experience greater temperature extremes. In addition, a blackened surface, due to partially combusted organic materials, would absorb more light and become warmer than a soil without a dark surface (Ahlgren and Ahlgren 1960). Soil temperatures may be elevated for months or years depending on the degree of organic matter consumption (Neary et. al. 1999). Such changes in the soil temperature regime would affect rates of biological activity in the soil, resulting in altered nutrient cycling regimes.

Soil Porosity and Detrimental Compaction

In the absence of future timber harvests, road construction, or other compacting activities, soil compaction is expected to decline and soil porosity is expected to increase. In the event of a future wildfire, severe soil heating may cause physical changes in soils, including a reduction in soil porosity (Clark 1994).

Alternative 1 – Proposed Action (Water Resource Indicators)

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen and Cottonwood Treatments

Measurement Indicator 1 – Acres of DFPZ andArea Thin Fuels Reduction, aspen and cottonwood treatments within sensitive (i.e. RHCAs and SMZs) and upland areas.

Under Alternative 1, mechanical equipment entry will be allowed into the outer edges of the RHCAs and SMZs based upon design features and SOPs (Ingalls Project EA, Appendix B) stated in the Ingalls project EA. Limited mechanical treatment will occur in the outer portion of the RHCAs where slopes are less than 25 percent. The canopy cover in RHCAs will be greater than 40 percent. This would prevent effects to stream temperatures by allowing stream shading and maintaining moister microclimates for fish and macroinvertebrates. Aspen and cottonwood stand treatment will follow applicable design features (Ingalls Project EA, Table 6) and SOPs (Ingalls Project EA, Appendix B) for treatment in RHCAs and are authorized by the RMO objectives.

Direct effects of mechanical treatment, pile burning, and underburning within sensitive and upland areas may include disturbance and displacement of soils, removal or consumption (underburning) of soil ground cover, and reduction in porosity and increase in soil compaction within these areas. These disturbances may lead to direct effects on water quality in the stream channels adjacent to the units. This could result in indirect effects to downstream beneficial uses through water temperature increases and sedimentation.

Direct effects of stream channel restoration work within Unit 003, an aspen/cottonwood treatment unit, would include stabilization of eroding steam banks, treatment of headcuts, and revegetation of streambanks. Indirect effects would include improvement in water quality due to reduced stream channel sedimentation and in improvement in riparian forest growing conditions.

The Forest Service water quality protection program relies on implementation of prescribed best management practices (BMPs). BMPs are monitored and tested for implementation and effectiveness to assess for potential direct and indirect effects from management activities. Those

BMPs tested have been shown to effectively meet practice objectives when properly implemented. There is a strong correlation between implementation of BMPs and measures of effectiveness (ground cover, lack of sediment delivery to channels, etc.) (USDA Forest Service 2009).

Additionally, the Plumas National Forest Annual Report for the Best Management Practices Evaluation Program (USDA Forest Service 2009) found that of the 81 evaluations conducted on the Plumas, only 3 rated a “fail” for BMP implementation, resulting in a BMP implementation rate of 96.3% (USDA Forest Service 2009). For the 51 evaluations of BMPs typically associated with timber and fuel management activities (T01, T02, T04, E08, E09, E11, and F25) in 2009, the implementation rate is 98% and the effectiveness rate is 96%. It is expected that by following the appropriate best management practices and project design features and SOPs there will be no detrimental direct or indirect effects from implementation of proposed activities associated with this alternative.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects.

Measurement Indicator 2 – Road density (miles per square mile) in the analysis subwatersheds.

The Proposed Action includes 14 miles of maintenance and reconstruction and 4.8 miles of obliteration of Forest System and Non-System Roads within the analysis subwatersheds. Road maintenance may consist of brushing, blading the road surface, and/or improving drainage. Road reconstruction would include installation of new drainage features to disperse runoff and correct several identified sources of road-generated sediment. Reconstruction would also improve several stream crossings and reduce the risk of erosion of the road prism during large flood events. Obliteration would involve one or more of the following: excavation of the road prism and placement of fill to restore the natural hillslope contour; subsoiling of the road surface restore hydrologic function and facilitate vegetative re-growth; and/or abandonment (if the road has become completely over grown with vegetation). Obliteration would also involve removing drainage structures, restoring vegetative cover, blocking access or some combination of these treatments. Under Alternative 1, road densities would be reduced by an average of 20 percent in the four analysis subwatersheds where road obliteration has been proposed (Light, Pebble, Ridge, and Sullivan subwatersheds). Road densities would remain unchanged in the remaining 12 analysis subwatersheds (Table 40).

Overall reduction in road-generated sediment through the obliteration of roads within the analyzed subwatersheds would be substantial in the long-term.

Road maintenance, reconstruction, and obliteration related to this alternative are expected to have a direct effect on the improvement and protection of water quality and adjacent riparian vegetation along Red Clover Creek, Lake Davis, and other unnamed drainages throughout the analysis subwatersheds along with having positive indirect effects on downstream water quality and beneficial uses. In addition, based upon the type and location of road treatments proposed in Alternative 1 and implementation of BMPs, any resultant sedimentation is expected to be minimal.

Table 40. Subwatershed Road Miles and Densities for Alternative 1.

Analysis subwatershed	Miles of Road	Road Density (mi/mi²)		Analysis subwatershed	Miles of Road	Road Density (mi/mi²)
Light	6.1	5.1		Pebble	1.1	1.6
Crystal	3.0	3.8		Bagley	5.2	4.7
Coldwater	10.2	4.3		Ridge	3.5	2.7
Turner	7.6	4.2		Old House	13.7	3.9
Red	3.4	3.1		Lightning	10.2	3.8
Contact	1.4	2.3		Big Grizzly	17.1	3.6
Wilson	2.1	3.5		Vulture	3.6	3.0
Marble	1.7	1.9		Sullivan	2.9	2.4

Cumulative Watershed Effects Analysis – Water (Alternative 1)

Measurement Indicator 3 – Equivalent Roaded Acres (ERA) values within analysis subwatersheds

Under Alternative 1, ERA values range from 5.2 to 13.5 percent of the sensitive areas and 2.8 to 14.5 percent of the upland areas in each subwatershed (Figure 14 & Figure 15).

Increases in ERA values from the Proposed Action, in the sensitive areas, range from 0.1 percent to 5.8 percent and less than 0.1 percent to 7.0 percent for upland areas in the analysis subwatersheds. Although most subwatersheds are below the upland TOC, the ERA total for the Big Grizzly subwatershed exceeds the determined upland TOC by 2.5 percent. In sensitive areas, the ERA values for the Light, Marble, Pebble, Red, Sullivan, and Turner are below the TOC. ERA values in the remaining 10 subwatershed exceed the established TOC value for sensitive areas by 0.5 to 5.5 percent.

ERA values would be increased as a result of the Proposed Action's mechanical treatments and underburning on acres within the analysis subwatersheds. Detrimental effects that may potentially result from increases in ERA include fluvial erosion from treated hillsides and compacted surfaces, resulting in delivery of fine sediment to adjacent stream channel buffer zones, which vary in width and are determined through analysis of streamflow regime, observed channel characteristics, and the presence or absence of fisheries.

The Big Grizzly subwatershed has an upland ERA value that exceeds the determined TOC (12 percent ERA) and therefore is at a higher risk of generating offsite cumulative watershed effects. Factors leading to the modeled increase in ERA include past and current timber and fuels reduction activities, existing road densities, and livestock grazing within the subwatershed. It is important to note that nearly half of the upland ERA value is comprised of very recent or current DFPZ fuels reduction that have been or will be implemented under the Grizz and Freeman Projects, which were designed in part to reduce the likelihood of catastrophic wildfire. ERA totals that exceed the TOC indicate that natural watershed hydrology may be significantly altered, particularly with respect to alterations of surface runoff patterns and timing. Such alterations can result in scour and degradation of adjacent stream channels and/or increased hillslope erosion over natural rates with potential delivery of fine sediment to streams. However, based upon stream and soil surveys along with several site visits, many of the sensitive areas in the Big Grizzly subwatershed have not been impacted to degree that has been indicated by the ERA model. Although the upland ERA value for the Big Grizzly subwatershed is above the TOC, project BMPs and design features for streamside areas, including slope restrictions and equipment exclusion zones, would assure that significant effects to water quality would not occur and downstream beneficial uses would not be impacted.

In addition, the Bagley, Lightning, Marble, Old House, and Wilson subwatersheds have high upland ERA values that are approaching, but do not exceed the TOC. Upland ERA values in these subwatersheds are greater than eight percent of the subwatershed area. However, as with the Big Grizzly subwatershed, the observed existing condition of stream channels and adjacent riparian buffers, along with implementation of project BMPs and design features, assure that significant impacts to water quality and beneficial uses would not occur in these subwatersheds. Adverse cumulative watershed effects due to implementation of the Proposed Action are not expected for any of the analysis subwatersheds.

ERA values for the sensitive areas of the Bagley, Big Grizzly, Coldwater, Contact, Crystal, Lightning, Old House, Ridge, Vulture, and Wilson subwatersheds exceed the determined TOC (eight percent ERA) and therefore are at a higher risk of generating offsite cumulative watershed effects. Similar to the upland areas, the modeled ERA values are the result of timber harvests, fuels reduction projects, roads, and livestock grazing. However, the observed existing condition of stream channels and adjacent riparian buffers, along with implementation of project BMPs and design features, assure that significant impacts to water quality and beneficial uses would not occur in these subwatersheds as a result of Alternative 1. Field surveys of the watersheds and associated stream systems that are above or near the TOC were conducted to verify stream channel and hillslope conditions and properly select project design elements that would reduce the risk of detrimental effects to the soil and water resources. No adjustment in ERA values was incorporated in the model analysis to account for project BMPs or design features. Additionally, it is important to mention that the equipment exclusion zones for RHCAs and SMZs were not removed from the total treatment acreage proposed in action alternatives. Therefore, ERA values for sensitive areas are conservative estimates within the analysis subwatersheds.

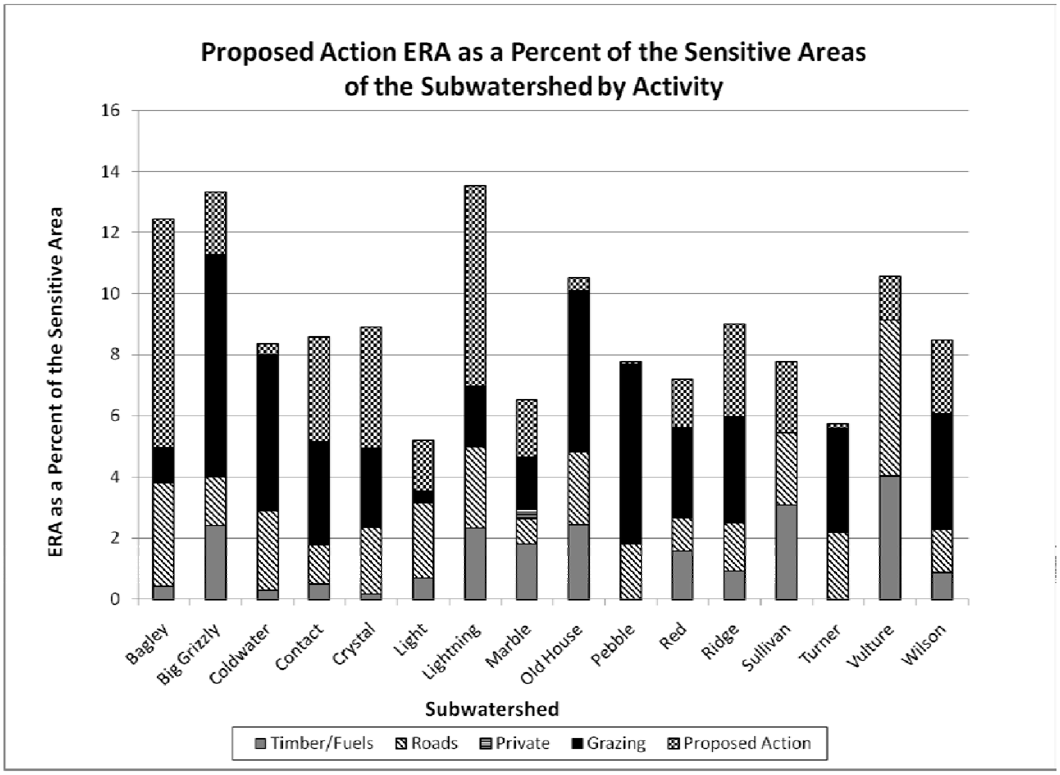

Figure 14. Alternative 1, the Proposed Action (PA): Equivalent roaded acres (ERA), shown as a percent of the sensitive area of each analysis subwatershed, broken down by land use.

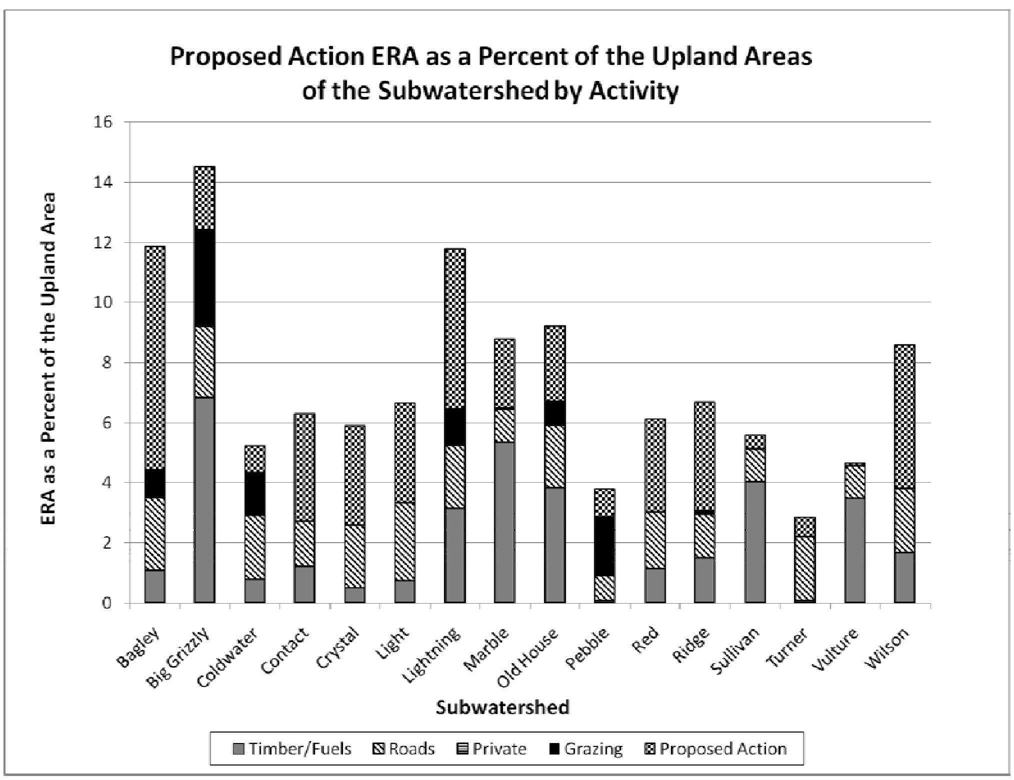

Figure 15. Alternative 1, the Proposed Action (PA): Equivalent roaded acres (ERA), shown as a percent of

the upland area of each analysis subwatershed, broken down by land use.

Alternative 1 – Proposed Action (Soil Resource Indicators)

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen and Cottonwood Treatments

Measurement Indicator 4 –Soil productivity (soil ground cover, fine organic matter and large woody material, soil porosity/compaction and soil buffing capacity) changes within DFPZ and Area Thin fuels reduction, Aspen and Cottonwood treatment units

By following the design features and Standard Operating Procedures outlined in the Ingalls Project EA and this report, any direct or indirect effects to soil condition under implementation of Alternative 1 would not be of a size or pattern that would result in a significant change in production potential for the project area. All standards and guidelines for soil productivity presented in the PNF LRMP and the SNFPA ROD would be met under the implementation of Alternative 1, as discussed below.

Sufficient soil cover is necessary to prevent soil erosion rates from exceeding the rate of soil formation. The stated long-term average rate of forest soil formation is approximately one ton of soil per acre per year (one ton per acre is equivalent to the thickness of two sheets of paper). It is not expected that hillside erosion over any given treatment area would exceed one ton per acre per year, however, on a site specific basis this erosion rate may be exceeded on individual landings, roads or skid trails.

As summarized in the 2007 HFQLG Soil Monitoring Report (Westmoreland 2008), Westmoreland and others conducted pre and post-harvest soil monitoring data collection and statistical analysis on the Lassen, Plumas and Sierraville District of the Tahoe National Forests between 2001 and 2007 as part of the HFQLG Forest Recovery Act monitoring program. To assess for existing conditions, planned treatment units were sampled pre-treatment from 2001 to 2004, post-treatment monitoring occurred on these units from 2004 to 2007. As a result, 52 units (39 thinning units, 11 group selection units and 2 mastication units) were analyzed for soil ground cover, large woody debris and soil compaction (loss of porosity) as they relate to standard and guidelines. Soil monitoring results are described below in their appropriate section.

Soil Cover

Operation of mechanical equipment within the proposed mechanical treatment units would result in a disturbance and possible loss of the existing ground cover. However, it is difficult to accurately predict treatment effects on effective ground cover. Harvest operations may increase activity fuels and effective ground cover, while pile burning and underburning reduces the cover of these materials. Mastication would increase soil cover as materials are broadcast away from the machine. The direct effects of increasing soil ground cover on-site ameliorates the potential for soil displacement and increases in overland flow that may influence indirect effects to off-site soil cover.

Skid trails and burn piles are other ways ground cover is reduced. However, there is a less of a concern over erosion associated with concentrated overland flow with burn piles because even though they lack ground cover vegetation, they are islands contained within surrounding vegetation. Burn pile estimates range from 5 to 10 per acre and 10 to 20 feet in diameter; based upon these estimates, burn piles would occupy roughly 1%-7% of a treated area. Ground cover lost from burn piles is in the form of dispersed islands where sediment transport would likely be trapped by the surrounding vegetation and is not of the same concern as larger barren strips created from skid trails.

In accordance with PNF LRMP and the Regulatory Environment section of this document, project standards for effective ground cover will determined by soil erosion hazards ratings. The 16 units with low EHRs will have a standard of 40% effective ground cover. The 33 units with a moderate EHR will have a standard of 50% effective ground cover. The remaining 8 units with a high EHR will have a standard of 60% effective ground cover. Survey data indicates that existing soil cover amply exceeds the 40% - 60% standard. For the 77 sets of pre- and post-treatment survey data that is available from the HFQLG soil monitoring program, large differences in post-treatment ground cover are apparent between different treatment types (Young 2010). The 51 thinning units averaged 80% soil cover post-project, while the 24 group selection units averaged 60% soil cover post-project.

Statistical analysis of the 52 thinning and group selection data sets available in 2007 determined statistically significant ($P < 0.05$) differences between pre- and post-project soil cover condition. For the 39 thinned units, the 95% confidence level described a post-project reduction in the areal extent of soil cover ranging from 9% to 15%. Average existing effective cover for the surveyed thinning units, including the aspen and cottonwood units, in Alternative 1 is 94%. Since existing effective cover exceeds 78% for all sampled units, even the higher end of the 95% confidence range for decrease in soil cover (a 15% decrease) is expected to leave the units with sufficient cover to meet the project standard of 40-60% post implementation ground cover standard. Standard Operating Procedures (Appendix B of the EA) assure compliance with the ground cover standard by incorporating mitigation methods that would leave slash and chip material on-site in units with deficient post-harvest soil cover.

For the 11 group selection units, the 2007 HFQLG soil monitoring data indicated a statistically significant and more dramatic reduction in post-project ground cover. For group selection units, the average decrease in the areal extent of effective soil cover was 48%, with a 95% confidence interval ranging from -36% to -62% (Westmoreland 2008). Average existing effective cover for the surveyed group selection units in Alternative 1 is 94%. As with the thinning units, the SOPs (Appendix B of the EA) would assure compliance with the 60% ground cover standard. Furthermore, a 2008 letter from the three Supervisors of the HFQLG Forests describes management techniques to bring Forests into compliance with soil standards (USDA Forest Service 2008). These techniques would result in a decrease for soil cover in group selection units that is much less substantial than the 48% decrease (on average) observed in the 2007 HFQLG monitoring report.

For the 2 mastication units, the 2007 HFQLG soil monitoring data indicated that because the pre-treatment conditions of the two mastication units were drastically different, the average values are not very meaningful (Westmoreland 2007). As previously mentioned, it is expected that mastication would increase soil cover as materials are broadcast away from the machine. The direct effects of increasing soil ground cover on-site ameliorates the potential for soil displacement and increases in overland flow that may influence indirect effects to off-site soil cover.

After the initial reduction in effective soil cover due to mechanical treatments, ground cover would increase substantially over the next 2 years due to needle cast and natural re-vegetation of the treated units. A significant reduction in soil cover would increase the risk of surface soil erosion temporarily in affected areas. While the average areal extent of effective soil cover for a unit is a good measure for analyzing soil productivity effects, actual soil erosion would be highly dependent upon the size and distribution of bare areas as well as site specific factors such as soil erodibility, slope magnitude, topographic variations that limit slope length, and configuration of the unit. The effect of short term reductions in soil cover for Alternative 1 would generally be inconsequential to soil erosion and productivity because contiguous bare areas would be isolated, relatively small, and well dispersed across the treated unit. Concentrated and contiguous removal of soil cover is most likely to occur in areas such as landings, skid trails, and temporary roads. For these features, soil erosion would be controlled by implementation of BMPs and SOPs, measures that include installation of waterbars and crossdrains and placement of post-logging slash on skid trails.

Organic Matter and Large Woody Debris

It is expected that from the actions of this alternative, organic matter would be directly affected by the removal of trees and treatment of slash material. Accurate prediction of treatment effects on surface fine organic matter is difficult but trends would likely be consistent with those observed for effective soil cover in the 2007 HFQLG soil monitoring report (described above). Operation of equipment within the harvest units is expected to displace existing organic matter and disturb shrubs and grasses. Mastication treatment units are expected to have an increase in organic matter as masticated debris is broadcasted away from the machine. The post-treatment depth and distribution of the organic layer depends on the slash treatment method selected to attain the ground cover and fuel loading design elements of the project.

Under this alternative, organic matter and soil nutrients may be affected by this project though soil displacement via road and landing construction, prescribed burns, burn piles, and removal of vegetative material from the site. Therefore it is imperative that the effects from the proposed activities be mitigated through the SOP retention requirements.

This alternative has the most acres proposed for pile burning and underburning of the action alternatives. Underburn treatments may reduce organic matter, but burning is expected to occur under prescribed conditions that would not result in complete combustion of the duff and litter layers.

Pile burning would decrease surface fine organic matter locally, but over time adjacent trees and shrubs would provide litter to cover the burned area. Fireline construction around prescribed burn areas and piles would create bare soil conditions. Over time, adjacent trees and shrubs would provide organic cover and levels of fine organic matter are expected to trend toward the existing condition. Soil cover mitigations required by project SOPs will also increase levels of fine surface organic matter and post-project levels are expected to be near or exceed 50%, particularly in the longer term (more than 2 years after treatment). In the short term, the extent and pattern of reductions in fine organic matter associated with Alternative 1 would not result in a significant change in production potential for the treated units. When available, organic matter will be redistributed over skid trails, landings, and roads that are proposed for obliteration.

Large woody material monitoring results from the 2007 HFQLG Soil Monitoring report stated that large woody material decreased from levels observed during pre-treatment monitoring. Only 62% of the thinning units and 18% of group selection units met the recommended guideline of 3 large down logs per acre under the post-project condition, whereas 85% of the thinning units and 73% of the group selection units met the guideline under the pre-project condition. Large down woody material was reduced more within group select units with only 2 out of the 11 units meeting the guideline, 3 of the 11 units having no logs pre-treatment, and 6 of the 11 units not meeting the guideline. In terms of the 40 thinning units monitored, 6 units had no logs in the pre-treatment, 8 units were reduced from meeting the guideline to not meeting it, and 25 units meeting the guideline pre- and post-treatment.

Based upon field observation while conducting soil surveys for the Ingalls Project, it appears that many of the units had very similar large woody material findings within proposed treatment units as found in the aforementioned pre-treatment monitoring results. If Alternative 1 were to result in large down woody material reductions similar to the 23.1% reduction within thinning treatment units and 54.5% reduction within group selection, many of the units would be at risk of not meeting this project’s large woody material standard of 10-15 tons per acre. However, the 2008 letter from the three Supervisors of the HFQLG Forests described above in the soil cover section also presented management techniques to bring Forests into compliance with soil standards (USDA Forest Service 2008). Those techniques, along with other standard operating procedures such as leaving down woody material on site or leaving cull logs at the stump rather than skidding them to the landing in areas deficient in large woody debris would ensure that the project standard for large woody material would be met.

It is not expected that the decreases in fine organic matter and LWD as a result of this alternative would result in detrimental direct or indirect effects to the water-holding capacity, nutrient retention, infiltration, and hydrologic function of the soil. This is based upon the proper implementation of project BMPs, design features, and SOPs.

Soil Porosity and Detrimental Compaction

Soil porosity is the volume of voids compared to solids for a given volume of soil. The porosity of the soil is important for gas exchange and water movement into and through the soil. Ground based management activities can potentially reduce porosity by compacting the soil. The degree of detrimental soil compaction varies with soil texture, soil moisture content at the time the activity takes place, the weight and ground pressure of the equipment used, and whether woody material remains in place to cushion the weight of equipment. Increases in the areal extent of detrimentally compacted ground are expected for treated units due to equipment traffic and the need for new skid trails, landings, and temporary roads.

Proposed treatment units are susceptible to detrimental compaction when the soil moisture content is near field capacity. Sandy soils and soils with high rock content are less susceptible to detrimental compaction. There is a high risk for detrimental compaction to occur in proposed treatment units with high clay content if operations occur when the soils have a moisture content that is near field capacity. To control the risk of detrimental compaction, SOPs for soil protection in Appendix B of the EA require that heavy equipment treatment operations occur only when the upper 8" of the soil profile is essentially dry. Additional Standard Operating Procedures for the Ingalls project state that based upon soil type, existing landings and skid trails used by the project and newly created skid trails with compacted soil, will be subsoiled using a wingtip subsoiling implement in accordance with the recommendations.

The use of heavy equipment and recurring stand entries increases the potential for a reduction of soil porosity and increase of soil compaction. The degree of soil compaction varies with soil texture and moisture content, while plant responses to compaction depend strongly on changes in the soil water regime (Gomez et al. 2002). Ongoing research has focused on the effects of soil compaction to long term soil productivity. Powers et al (2005) recently published the ten-year results of the Long Term Soil Productivity (LTSP) study, a study initiated in 1989 and comprised of more than 60 sites, including sites in the Sierra Nevada. The study focuses on two soil condition indicators readily affected by management activities, soil compaction and surface organic matter. The national ten-year results indicate that soil compaction effects on total biomass productivity (all vegetation within a site, not just tree growth) differs depending upon soil texture, along with other factors such as initial bulk density, rock content, and climate.

Soil porosity/compaction monitoring results reported in the 2007 HFQLG Soil Monitoring report stated that a review of monitoring data indicates that legacy compaction is commonplace. Most of the detrimental compaction observed post-project also existed pre-project (Young 2010). Statistical analysis for 40 thinned units and 11 group selection units determined that the mean post-project areal extent of detrimental compaction as not statistically different from the pre-project mean. Confidence intervals indicated broad ranges that suggested both a trend toward increasing the extent of detrimental compaction and a trend toward decreasing extent.

The existing areal extent of detrimentally compacted soil for proposed treatment units varies widely, from 0% to 34%. For units that indicate widespread compaction under the existing condition, subsoiling SOPs for Alternative 1 would likely result in a decrease in the extent of detrimentally compacted soil. For any mechanical harvest, the extent and degree of compaction depends on site-specific soil conditions such as texture and rock fragment content, moisture content at the time of operations, and harvest equipment features. The soil texture classes within the units proposed for mechanical treatment are generally sandy to loamy, resulting in compaction potentials that range from slight to moderate. The Ingalls project SOP for wet weather operations will minimize soil compaction in the mechanical treatment units. By following the SOPs and utilizing existing skid trails where feasible, direct and indirect effects associated with detrimental compaction due to project activities are not expected to be of a size or pattern that would result in a significant change to soil production potential.

In addition to skid trails and landings, 8.4 miles of temporary roads would have to be constructed to provide access to the landings from system roads. Depending on soil type, construction and use of these features can compact soils and decrease soil porosity. In order to mitigate these effects, the Standard Operating Procedures (SOPs) for this project state that existing landings and skid trails used by the project and newly created skid trails, landings, and temporary roads with compacted soil would be subsoiled using a wingtip subsoiling implement where specified by the District's physical scientist. In addition, the obliteration of 4.8 miles of roads under this alternative would alleviate some of the compaction effects.

Soil Buffering Capacity and Borax Effects

Pile burning and underburning may cause short-term alterations to soil pH and nutrient cycling at a relatively small scale (Raison 1985). Based upon the location, areal extent, and degree of pile burning and underburning of the two action alternatives, it is not expected that there will be a detrimental effect to soil buffering capacities within the analysis subwatersheds. In addition, Borax (common name borax; chemical name sodium tetraborate decahdrate) is not expected to change soil buffering capacity. Borax is generally active in the soil. Boron from Borax is absorbed by the mineral portion of the soil and is absorbed from the soil by plants. Boron is an essential plant nutrient which naturally occurs in the soil at concentrations of 5 to 150 parts per million. Borax remains unchanged in the soil for varying lengths of time, depending on soil acidity and rainfall. The average persistence is one or more years. Borax is less persistent in acid soils and in areas with high rainfall. Soils in the project area are mostly slightly acidic, with pH values ranging from 6.0-7.0. Soil microorganisms do not break down Borax. Borax is partially soluble in water, and the potential for leaching into ground water or surface water contamination is low (Information Ventures Inc. 1995). All action alternatives will treat an average of 0.9 pounds of borax per acre within the project treatment units. Soil buffering capacity and Borax direct and indirect effects are expected to remain largely unchanged by all action alternatives therefore will not be discussed under Alternative 3.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects.

Measurement Indicator 5 –Miles of road maintenance, reconstruction, obliteration and

temporary road construction within analysis subwatersheds.

Under Alternative 1, there are approximately 96 miles of roads throughout the analysis subwatersheds. As a result of the road obliteration proposed with this alternative, there will be a reduction of approximately 5 miles of roads within the analysis subwatersheds. As previously mentioned, it is assumed that most roads within the analysis subwatersheds would continue to exist and be maintained at their current levels. Four of the analysis subwatersheds would receive some form of road obliteration with this alternative, thereby having a positive direct and indirect effect on soil productivity and hydrologic function within these subwatersheds. Detrimental soil effects associated with temporary road construction would occur with this alternative. However, these effects are expected to be limited to direct effects only as all applicable BMPs will be followed in constructing roads as part of this alternative. Indirect effects will continue to be monitored with the BMP implementation and effectiveness evaluations as discussed in the 2010 Plumas National Forest Annual Report for the Best Management Practices Evaluation Program.

Cumulative Watershed Effects Analysis – Soils (Alternative 1)

Soil Cover

A reduction in ground cover is likely to be short lived if nearby overstory trees remain intact. Over time, litter from trees and shrubs would contribute to the development of effective ground cover in bare areas. A high-intensity wildfire entering an area proposed for treatment would result in a much greater reduction in ground cover than the proposed treatments alone. The fuel reduction treatments proposed under Alternative 1 would reduce the likelihood of that type of future high-intensity wildfire. It is unlikely that implementation of Alternative 1 would add any negative cumulative effects on soil cover.

Organic Matter and Large Woody Debris

Following the proposed treatments, organic matter on the soil surface would decrease in some areas, due to mechanical displacement, while organic matter would increase in other areas due to additions of treated slash material and implementation of the LWD retention standard. This may result in greater heterogeneity of the forest floor. Patches of organic matter would provide habitat for soil invertebrates and microorganisms. Patches of bare areas would be susceptible to local erosion. Increases in woody materials on the forest floor due to lop and scatter or mastication treatments may cause short term changes in decomposition and carbon and nutrient dynamics in affected areas. Microorganisms that decompose wood would immobilize nitrogen and other nutrients while decaying the woody material. As the wood decomposes, those nutrients would be released and made available to plants and other organisms (Swift 1977).

It is not expected that the decreases in fine organic matter and LWD as a result of this alternative would result in detrimental cumulative effects to the water-holding capacity, nutrient retention, infiltration, and hydrologic function of the soil. This is based upon the proper implementation of project BMPs, design features, and SOPs.

Soil Porosity and Detrimental Compaction

Depending on soil type, construction and use of skid trails and landings can compact soils and decrease soil porosity. In order to mitigate these effects, the Standard Operating Procedures (SOPs) for this project (Ingalls project EA, Appendix B) state that existing landings and skid trails used by the project and newly created skid trails, landings, and temporary roads with compacted soil would be subsoiled using a wingtip subsoiling implement where specified by the District's physical scientist. It is important to note that the SOP requirements for subsoiling were established from recommendations made by the Regional Soil Scientist as a result of a field review of subsoiling that was conducted June 12-14, 2006 on the Plumas and Tahoe National Forest by personnel from each forest (USDA Forest Service 2006). In addition, the obliteration of 4.8 miles of roads under this alternative would ameliorate some of the compaction effects.

Cumulative effects related to soil porosity and detrimental compaction as a result from actions associated with this alternative will be mitigated through subsoiling of compacted soils along with the implementation of other soil protection measures and mitigations.

Alternative 3 – Non-Commercial Funding Alternative (Water Resource Indicators)

Alternative 3 differs from Alternative 1 through changes made in the prescriptions for units and

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen and Cottonwood Treatments

Measurement Indicator 1 – Acres of DFPZ and Area Thin fuels reduction, aspen and cottonwood treatments within sensitive (i.e. RHCAs and SMZs) and upland areas.

The total treatment area proposed for this alternative is approximately 2,630 acres, which is 694 acres less treatment than Alternative 1. Mechanical treatments under Alternative 3 would be reduced by 161 acres in sensitive areas and 533 acres in upland acres when compared Alternative 1. Hand thin and underburn acreages would remain unchanged when compared to Alternative 1.

Any differences in effects to water quality from those discussed for Alternative 1 as a result of these differences in proposed treatments would be slight and localized. By following the appropriate best management practices, project design features and SOPs there will be no detrimental direct or indirect effects from implementation of proposed activities associated with this alternative. Alternative 3 does not provide the beneficial indirect effects to water quality that would result from the stream channel stabilization work within unit 003.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects.

Measurement Indicator 2 – Road density (miles per square mile) within the analysis subwatersheds.

Alternative 3 includes 13.3 miles of maintenance and reconstruction and does not include road obliteration work or new construction. As a result of this, road densities, road stream crossings, and elimination of routes causing resource damage will not change when compared to the previously discussed Alternative 2.

Cumulative Watershed Effects Analysis (Alternative 3)

Measurement Indicator 3 – Equivalent Roaded Acres (ERA) values within analysis subwatersheds .

Under Alternative 3, ERA values for the analysis subwatersheds range from 3.5 to 13.2 percent of the sensitive areas and 2.6 to 13.9 percent of the upland areas in each subwatershed (Figure 16 and Figure 17). ERA increases from the No Action Alternative range from 0 to 6.3 percent of the upland area and 0 to 4.4 percent of the sensitive areas in the analysis subwatersheds. Although most subwatersheds are below the upland TOC, the ERA total for the Big Grizzly subwatershed exceeds the determined upland TOC by 1.9 percent. In sensitive areas, ERA values exceed the sensitive TOC in the Bagley, Big Grizzly, Lightning, Old House, Ridge, Sullivan, and Vulture subwatersheds by 0.1 to 5.2 percent.

In addition, the Bagley, Lightning, and Old House subwatersheds have high upland ERA values that are approaching, but do not exceed the TOC. Upland ERA values in these subwatersheds are greater than eight percent of the subwatershed area. ERA values for the sensitive areas of the Contact, Crystal, Marble, Pebble, Red, Coldwater, and Wilson subwatersheds are also high, but do not exceed the TOC. ERA values for the sensitive areas in these subwatersheds are greater than 6 percent.

For Alternative 3, these differences in ERA values do not result in a substantial change from the risk of cumulative watershed effects that was presented for Alternative 1. Field surveys of the watersheds and associated stream systems that are above or near the TOC were conducted to verify stream channel and hillslope conditions and properly select project design elements that would reduce the risk of detrimental effects to the soil and water resources. Implementation of project BMPs and design features, along with the observed existing condition of stream channels and adjacent riparian buffers, assure that significant impacts to water quality and beneficial uses would not occur in these subwatersheds as a result of Alternative 3.

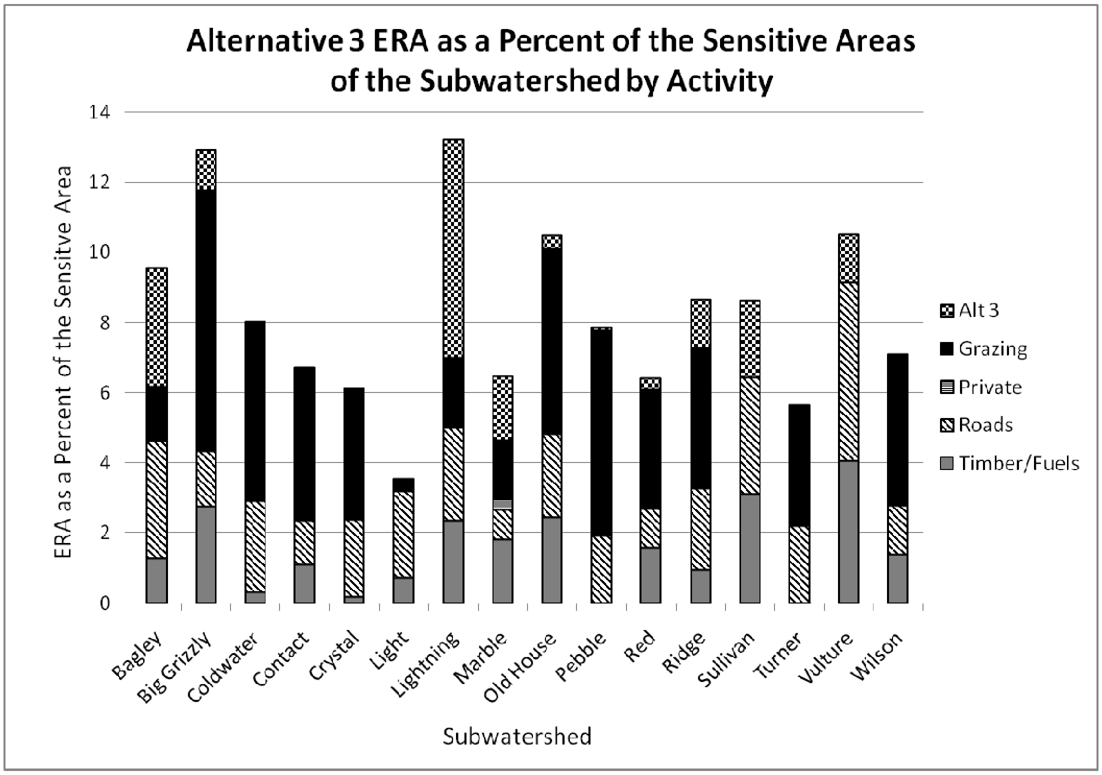

Figure 16. Alternative 3: Equivalent roaded acres (ERA), shown as a percent of the sensitive area of each analysis subwatershed, broken down by land use.

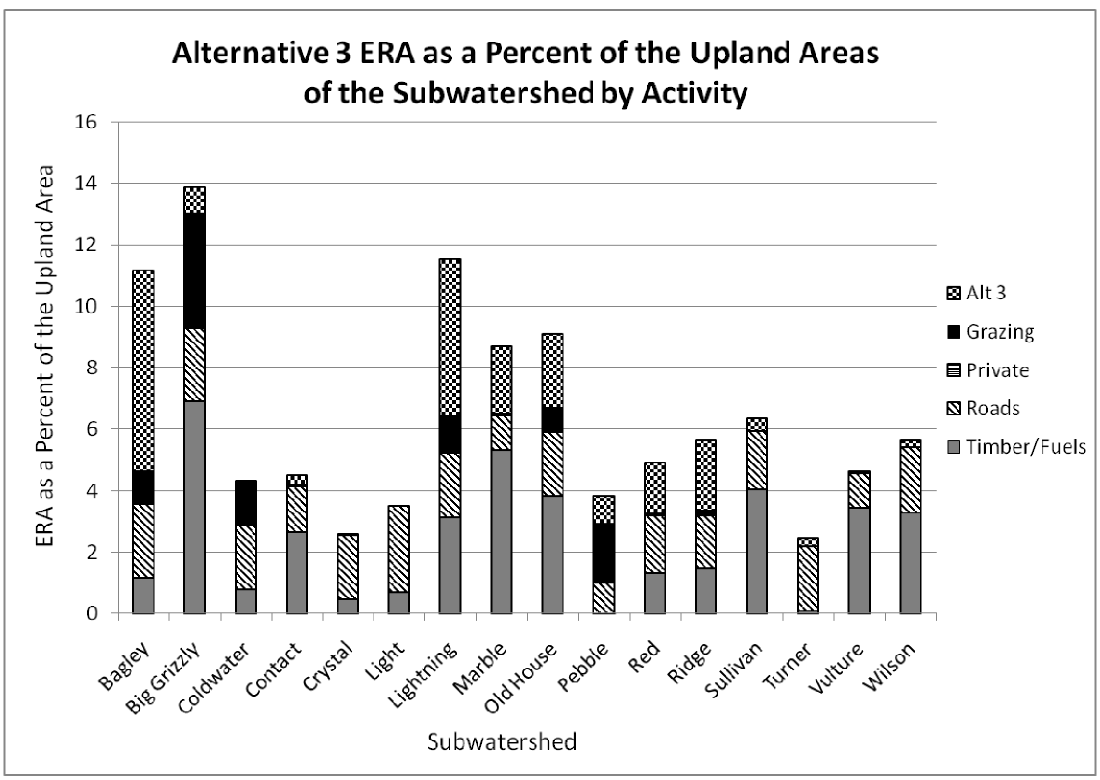

Figure 17. Alternative 3: Equivalent roaded acres (ERA), shown as a percent of the upland area of each

analysis subwatershed, broken down by land use.

Soil Resource Indicators (Alternative 3)

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments, Aspen and Cottonwood Treatments

Measurement Indicator 4 –Soil productivity (soil ground cover, fine organic matter and large woody material, soil porosity/compaction and soil buffing capacity) changes within DFPZ and Area Thin fuels reduction, Aspen and Cottonwood treatment units

Alternative 3 includes 1507 acres of mechanical treatment, 780 acres of hand thinning with under burning, and 343 acres of underburning. Direct and indirect effects to the soil productivity measures listed above will essentially be the same as Alternative 1, with the only difference being the amount of acreage mechanically treated. As stated above, amount of mechanical thinning has been reduced by 694 acres when compared to Alternative 1. The changes in the silvicultural prescription for the DFPZ units under Alternative 3 are not expected to produce effects that differ from those discussed under Alternative 1.

Direct and Indirect Effects of Providing Road Access to Meet Project Objectives while Reducing Transportation System Effects.

Measurement Indicator 5 –Miles of road maintenance, reconstruction, obliteration and temporary road construction within analysis subwatersheds.

Road restoration work on routes contributing excessive resource damage would not occur under this alternative. Under Alternative 3, the overall direct and indirect effects of road maintenance and temporary road construction would be effectively the same as Alternative 1. Localized improvements to the soil resource that would result from road restoration work would not occur under this Alternative.

Cumulative Effects Analysis – Soils (Alternative 3)

Cumulative effects to soil cover, organic matter, large woody debris, soil porosity, and detrimental compaction under Alternative 3 will be the same as what was previously discussed under Alternative 1. The changes in silvicultural prescriptions under this alternative will not result in a departure from the conditions presented under Alternative 1.

Botany Biological Evaluation

Introduction

The purpose of this Biological Evaluation (BE) is to provide an analysis of the Proposed Action and alternatives in the Ingalls Project Environmental Assessment and to determine whether they would result in a trend toward a Sensitive species becoming Federally listed as Threatened or Endangered under the Endangered Species Act (1973, as amended).

This biological evaluation documents potential effects from this project on *Astragalus lentiformis* (lens-pod milk-vetch) and *Ivesia sericoleuca* (Plumas ivesia), other Forest Service Region 5 Sensitive plant and fungi species, which are known to occur or have potential to occur within the project area. No other currently listed Forest Service Sensitive species are known or expected from the project area.

Analysis Methodology

The analysis of effects on rare plant species was a three-step process (FSM 2672.43). In the first step, all listed or proposed rare species that were known or were believed to have potential to occur in the analysis area were identified. This list was developed by reviewing the U.S. Fish and Wildlife List for the Plumas National Forest (USDI 2009), USDA Forest Service Region 5 Sensitive Species List (USFS 2006), Plumas National Forest rare plant records and geodatabases and California Natural Diversity Database records (CNDDB 2009).

The second step involved field reconnaissance surveys. The Ingalls Project area was reviewed using aerial photographs, soils maps and known occurrences to help determine potential habitat for rare species. Survey unit areas received intuitive survey coverage having a high potential for scoped species to occur. Therefore, surveys were conducted to cover at least 50% of the area with walking transects. Complete surveys were conducted at all contractor-discovered special habitat sites for the scoped species and at all known and contractor-discovered sensitive and special interest species sites for scoped species.

The project area was surveyed for vascular plants in 2007 by professional botanists. Non-vascular plant surveys also were conducted in 2007 by the Forest bryologist. Past surveys conducted as part of other projects in or near the project area include: Lovejoy Grizz survey 2005, Walker Grizz survey 2005, Mabie DFPZ 2002, Freeman Group Select and DFPZ 2004, Layman Fire Salvage Sale 1990-92, Ingalls Timber Sale 1984-86, Long Valley & Willow Creek 2 Grazing Allotments, Ravine Salvage Sale 1990, Ravine 2 Salvage Sale 1993, Long Valley Timber Sale 1980-95, Camp Layman RAC, Humbug DFPZ and Beckwourth Ranger District general noxious weed survey program.

Field surveys were designed around the flowering period and ecology of the rare plant species identified in step one. For each rare plant site found, information was collected that described the size of the occurrence, habitat characteristics and identified any existing or potential threats. Location information was collected using a Global Positioning System (GPS).

All of this information was used in step three of the analysis—conflict determination. Data were imported into a Geographic Information System (GIS) and used to analyze proximity to treatment units, identify detrimental effects and develop mitigation measures (see the Specific Design Features or Mitigations section). For management and record keeping purposes, occurrences of sensitive plants and noxious weeds may be divided into and recorded as suboccurrences but they will be discussed here as occurrences.

Insert Cumulative Effects analysis area definition for botanical resources.

Affected Environment/Environmental Consequences

There are two sensitive plant species that are known to occur within the analysis area, the lens-pod milk-vetch (*Astragalus lentiformis*) and the Plumas ivesia (*Ivesia sericoleuca*).

Affected Environment for *Astragalus lentiformis* (lens-pod milk-vetch)

There are 70 documented occurrences of this perennial herb, all of which are located within the boundaries of the Plumas NF. Though sometimes locally numerous, this species' range is very restricted being limited to the southeastern portion of the Beckwourth RD, worldwide. This plant is known to grow in Plumas County from Squaw Valley, Lake Davis and Claireville Flat east to Frenchman Lake. It usually is found on bare volcanic soils, between 4,500 and 6,500 feet in elevation in eastside pine, eastside pine/sagebrush scrub, or sagebrush scrub/grassy flats. It also occasionally is found in less open eastside pine forest where enough light reaches the ground to support a scattered shrub layer; however it appears less vigorous in this micro-habitat. The plant's response to decreased light and increased duff (principally pine needles) is to grow more upright and to produce fewer leaves, flowers and fruits. This last type of habitat is thus considered to be less than optimal for the plant and is thought to become less suitable over time if the shrub and canopy coverage increases.

The trend for this narrow endemic is unknown. Threats from management activities include fire suppression, livestock grazing, timber harvest, road construction, mining, reservoir construction and utility line construction. Botanists on the Plumas National Forest have observed that it is a disturbance follower that probably evolved with the natural disturbance of fire (USFS 2005a). With 100 years of fire suppression, the species is found mainly in areas where human caused disturbance regimes occur. Though this species has been found in areas that have been disturbed, the intensity, extent and frequency of the disturbance(s) has not been quantified in a manner that facilitates the development of prescriptions that consistently mimic historical disturbance regimes.

There are 9 occurrences, totaling 161 acres of lens-pod milk-vetch within the analysis area. Of those only 8 occurrences totaling 54 acres are within 100 feet of treatment units.

Environmental Consequences for *Astragalus lentiformis (*lens-pod milk-vetch)

Alternative 2 – No Action Alternative

Direct and Indirect Effects

There would be no lens-pod milk-vetch sites affected under Alternative 2, because there would be no action taken at this time.

Though there are no direct effects from the no-action Alternative, there are possible negative indirect effects from no action. Indirect effects from the No-action Alternative would be those associated with continued live and dead fuel accumulation with the current and future threat of wild fire. The lens-pod milk-vetch prefers early seral stage habitat. An increase in canopy cover and continued accumulation of down wood and leaf litter as a result of no action could be detrimental to this species. By not taking action through prescribed burning, the canopy, wood and duff layer would not be reduced in the surrounding habitat. Though the population may persist at its current level, it may not have additional ideal habitat in which to expand. If it does not continue to experience natural or anthropogenic disturbances periodically in the future, then eventually the forest canopy would close in and create conditions for more shade tolerant species to out-compete the lens-pod milk-vetch for light and other resources.

Continuing live and dead fuel accumulation increases the risk of high intensity wildfire. It is impossible to determine where, when and how a wildfire may enter an area, making any calculations of effects of wildfire to Sensitive plant populations unpredictable. Many times the effects of fire suppression can have larger impacts to Sensitive plants and their habitat than the wildfire itself and actual effects often depend on fire timing and intensity. With the No-action Alternative, stands would not be thinned or burned. As a result, both ladder and surface fuels would continue to increase over time, leading to an increase in the risk of a high intensity wildfire. High intensity fire may kill sensitive plants and affect soil seed sources. If no action is taken the potential for negative effects from a wildfire would be greater.

Cumulative Effects for Alternative 2

Cumulative effects for the No-action Alternative may result from ongoing firewood cutting, Christmas tree cutting, cattle grazing and high-intensity fire. Cumulative effects of the two activities were discussed under Alternative 1 and apply here. Risk of high-intensity wildfire is probably the most important factor contributing to potential cumulative effects of the No-action Alternative. The area surrounding the lens-pod milk-vetch population has signs of fire exclusion. Historically, the eastside pine habitat would have experienced frequent low- to moderate-intensity fires as opposed to high-intensity stand-replacing fires. Fuel loads are above desired levels in the stands surrounding some populations of lens-pod milk-vetch. Without treatment, fuel loads would increase and later pose risk of high intensity wildfire. Quantifying the threat a wildfire poses to the sensitive species is difficult since the species is dependent on fire, but a stand-replacing wildfire may be detrimental. There is potential for the lack of prescribed fire under the No-action

Alternative to contribute toward declining habitat suitability for lens-pod milk-vetch which has historically relied on some level of disturbance to maintain its place in the plant community.

Noxious weeds would continue to pose a threat, though they are not as likely to be introduced as they would be with the action alternatives. Without project activities to introduce weeds, introduction would be limited to other vectors such as firewood cutting, Christmas tree cutting, cattle grazing or wildfire suppression activities. The near-term risk of introduction and spread of noxious weeds is lower under the no action alternative than it is under the other alternatives. As the risk of wildfire increases with fuel build up over time the risk of noxious weed introduction from suppression activities would also increase.

Cattle grazing will continue in the analysis area and may affect lens-pod milk-vetch populations. Cattle grazing may harm or kill plants by trampling and may reduce reproduction rate.

Alternative 1 – Proposed Action

Direct Effects

There are 8 documented occurrences of lens-pod milk-vetch, totaling 54 acres within 100 feet of treatment units in Alternative 1. For management purposes these occurrences may be recorded as suboccurrences but they will be discussed here as occurrences. Parts of some affected occurrences would remain undisturbed in control areas. The control areas will be flagged and avoided. They would remain undisturbed to ensure that some lens-pod milk-vetch plants be allowed to produce mature seeds. Disturbed ground adjacent to control areas would provide suitable habitat for seeds to germinate and establish new individuals. Control areas are listed by occurrence number and unit identification number in table form in Appendix C. Sixty-six percent of the 161 acres of lens-pod milk-vetch in the analysis area is at least 100 feet away from any treatment unit and would not be disturbed by project activities.

The interim management prescription will be applied. Prescribed fire will be used to treat ASLE7_012 in units 45, 47 and 49. A control area in unit 48 would protect portions of ASLE7_012 from direct disturbance from the proposed mechanical thin activities. Another control area would protect ASLE7_044 in unit 13 from any direct impacts. Piles would not be constructed on occurrences of less than 50 individuals or less than ¼ acre in area. Sixty-six percent of the 161 acres of lens-pod milk-vetch in the analysis area is at least 100 feet away from any treatment unit and would not be disturbed by any project activities. Three of the nine lens-pod milk-vetch occurrences in the analysis area will have control areas that protect portions of the occurrence. Control areas would be flagged and avoided.

Direct and Indirect Effects of DFPZ and Area Thin Fuels Reduction Treatments (Alternative 1)

There are portions of 6 occurrences of lens-pod milk-vetch in mechanical thinning units. The affected portions of those 6 occurrences total approximately 22 acres. There are portions of 2 occurrences of lens-pod milk-vetch in hand thinning units. The affected portions of those 2 occurrences total approximately 32 acres.

There may be both beneficial and detrimental indirect effects to lens-pod milk-vetch. This is a disturbance following species and although some plants may be damaged or killed by thinning activities, the undisturbed portions of these occurrences would be able to produce seeds. Thinning activities such as heavy equipment operation would provide suitable habitat for those seeds to germinate by creating bare soil. As explained above a closed canopy is not the optimal habitat for this species. Mechanical thinning and mastication followed by underburning together would reduce the canopy and ground fuels to a greater extent than any of the activities alone. It is likely that this would improve habitat conditions by providing additional open canopy and pockets of disturbed ground that the sensitive plants could colonize. Existing plants are likely to respond with increased vigor and seed production. Applying variable activities across the landscape may create a mosaic of disturbances favorable to the species. However, it is possible that the combination of activities all in one stand potentially could degrade habitat by creating too much disturbance. This could limit the expansion of lens-pod milk-vetch from the adjacent population.

There are portions of 2 occurrences of lens-pod milk-vetch in underburning units. The affected portions of these occurrences total approximately 12 acres. Underburning in eastside pine habitat may mimic natural fire disturbance by reducing the thickness of the duff layer and opening up small pockets of canopy. This ground disturbance may provide better conditions for the establishment of lens-pod milk-vetch from the nearby population. However, it is possible that underburning would provide too low or too high of an intensity, or it may not be done frequently enough for the needs of lens-pod milk-vetch. In this case, underburning may not provide the benefits of habitat improvement.

Underburning in spring may kill some lens-pod milk-vetch plants. Fall burning is unlikely to damage plants as they would have already dispersed mature seeds. This is a perennial species that has been observed by PNF botanists to respond favorably to underburning. The loss of some individuals is likely to be compensated for by new individuals germinating and increased vigor of surviving plants.

Bare ground created by burning, fireline construction, thinning, and other proposed activities increases the risk of noxious weed invasion which may offset any benefits of increased habitat. If noxious weeds were to invade the treatment area, they potentially could take over portions of the lens-pod milk-vetch habitat and eventually reduce numbers of plants if not treated properly. Following standards and guidelines would greatly reduce the risk of noxious weed invasion.

Direct and Indirect Effects of Aspen and Cottonwood Treatments (Alternative 1)

There are no sites of lens-pod milk-vetch found within 100 feet of the aspen treatment unit under Alternative 1. Therefore there would be no direct or indirect effects expected to lens-pod milk-vetch from implementation of improving aspen stand growing conditions under this alternative.

Direct and Indirect Effects of providing road access to meet project objectives while

reducing transportation system effects (Alternative 1)

There would be direct effects to the lens-pod milk-vetch from activities that maintain and improve the transportation system within the project area. These activities would be necessary to provide the access needed to meet project objectives while reducing transportation system effects in the project area. Under Alternative 1 there is one occurrence of lens-pod milk-vetch that would be directly affected by the proposed road obliteration. This occurrence (ASLE7_008B) is along a non-system road identified as road 111A. The road is proposed to be treated by subsoiling through the occurrence. This action will disturb approximately 0.07 acres (3000sq ft) of a 60-acre occurrence. The remainder of the occurrence will be undisturbed; it lies in a no treatment unit of the DFPZ. Some plants would probably die as a result of subsoiling. This is a disturbance following species and the subsoiling would provide suitable conditions for new individuals to germinate and become established. The undisturbed 59-acre portion of this occurrence would provide a seed source to germinate in the suitable habitat created by subsoiling.

Cumulative Effects for Alternative 1

Other future foreseeable projects include ongoing firewood cutting, Christmas tree cutting, cattle grazing, recreation, Lake Davis trail, Blakeless Underburn, Red Clover Watershed Restoration, Red Clover Poco Watershed project and the PNF Public Motorized Travel Management. These activities have potential to be beneficial and harmful. As mentioned above, lens-pod milk-vetch is a disturbance follower, most likely following the natural disturbance of fire. It also is associated with human caused disturbances such as roads, powerlines, skid trails and other edge habitat.

Disturbances that create bare ground and open the canopy may benefit this species by providing additional habitat into which seeds can disperse, germinate and become established. Therefore, activities such as firewood cutting, Christmas tree cutting and underburning may provide those habitat conditions conducive to the species establishment and expansion.

Cattle grazing will continue in the analysis area and may affect lens-pod milk-vetch populations. Cattle grazing may harm or kill plants by trampling and may reduce reproduction rate.

The effects of the Blakeless Underburn project to the lens-pod milk-vetch are nearly identical to the described above under the heading: “Direct and Indirect Effects of Reducing fuel loads”. Existing and future portions of the Lake Davis trail have been planned to avoid impacts to lens-pod milk-vetch.

The Red Clover Prop 50 Watershed Restoration and Red Clover Poco Watershed projects were designed to avoid the lens-pod milk-vetch occurrences and would not directly affect the species. Red Clover Prop 50 Watershed Restoration was implemented in 2010. A follow-up treatment to that project is scheduled to occur in 2011. The follow-up treatment will be consistent with the proposed action and will comply with all mitigations that were required in the original environmental analysis for that project. Indirect and cumulative effects from these two projects are unlikely because the lens-pod milk-vetch is not found in the wet meadows or riparian areas where the project activities would occur.

The PNF Public Motorized Travel Management Final Environmental Impact Statement (FEIS) has designated routes for off-highway vehicles within the Ingalls project area. However none of those routes are within 100 feet of lens-pod milk-vetch occurrences. The process of designating routes included evaluating impacts to lens-pod milk-vetch. There are approximately 2900 acres of lens-pod milk-vetch documented on the PNF. The FEIS designated trails with the potential to impact approximately 1% (30 acres) of that area.

Cumulatively, if moderate disturbance is applied on a landscape level this should benefit the species in a wider area. Such activities have potential to kill individuals or interrupt reproductivity where individuals are present on the landscape. Firewood cutting and hazard tree removal within an occurrence may kill individual plants if trees are fallen on them. Also, these activities may contribute to fuels on the ground where limbs are cut and left from the firewood. These fuels may bury plants and contribute to some fuel loading in the stand. Contribution to fuel loading would be minimal and not be expected to add enough fuel to add to risk of stand-replacing fire that could be harmful to the plants.

Additionally, as mentioned previously in the "General Effects, Indirect Effects of Underburn and Pile Burn Section", burning following other anthropogenic disturbances can increase the risk of noxious weed invasion beyond that of any activity alone. Noxious weeds would continue to pose a threat to native plant habitat and sensitive plant species. With the underburn activities prescribed in the Proposed Action that would reduce ground fuels in the stand, noxious weeds can more easily invade the area. Weed invasion introduced into the adjacent stand eventually could move into the sub-occurrence and reduce the size of the milk-vetch population. Cumulatively, if this disturbance is applied on a landscape level without standard operating procedures, noxious weeds could easily become established. Following standards and guidelines would greatly reduce the cumulative effects of noxious weeds.

Not enough is known about the amount and type of disturbance favorable to the species to develop management prescriptions that mimic historical disturbance regimes. Too much disturbance or the wrong kind of disturbance may kill individual plants, inhibit reproduction and reduce habitat. It is known that the species would colonize and grow well in disturbed areas. Therefore, the cumulative activities are expected to provide suitable habitat by creating pockets of light to moderate disturbance across the landscape.

Alternative 3 – Non-Commercial Funding Alternative

Direct and Indirect Effects

There are eight documented occurrences totaling approximately 54 acres of lens-pod milk-vetch within 100 feet of treatment units in Alternative 3. The direct and indirect effects described above in the general effects of the action alternatives on p. 13 apply to alternative 3. The more specific direct, indirect and cumulative effects to the lens-pod milk-vetch of alternative 1 described on p. 20 also apply to Alternative 3with the following exception. The road obliteration on road 111A would not occur. The 0.07 acres of occurrence ASLE7_008B would not be impacted by road work under Alternative 3.

Several control areas will be implemented to protect portions of the occurrences that would be directly affected. The control areas will be flagged and avoided. They would remain undisturbed to ensure that some lens-pod milk-vetch plants be allowed to produce mature seeds. Disturbed ground adjacent to control areas would provide suitable habitat for seeds to germinate and establish new individuals. Control areas are listed by occurrence number and unit identification number in table form in Appendix C.

Cumulative Effects for Alternative 3

The cumulative effects for Alternative 3 are the same as those for Alternative 1. Alternative 3 eliminates mechanical thin treatment on 695 acres including the 95 acres of treatment to enhance aspen and cottonwood population. However, the number of occurrences and acres of lens-pod milk-vetch affected under Alternative 3 would be identical to Alternative 1(See tables 2 and 3 for exact numbers).

Affected Environment of *Ivesia sericoleuca* (Plumas ivesia)

One occurrence of Plumas ivesia is within the analysis area. Although it is not within 100 feet of any treatment unit it is addressed here because it is within the analysis area. Approximately 0.1 acres of this 1.5- acre occurrence fall within the analysis area.

Environmental Consequences for *Ivesia sericoleuca* (Plumas ivesia)

Alternative 2 – No Action Alternative

Direct and Indirect Effects

There would be no Plumas ivesia sites or acres affected under Alternative 2, because there would be no action taken at this time. There is very little canopy cover within 100 feet from the one known occurrence in the analysis area. There is very little fuel and the likelihood of wildfire is very low. Direct and indirect effects to this species from the No Action alternative are very unlikely.

Cumulative Effects for Alternative 2

There would be no cumulative effects to the Plumas ivesia as a result of implementing Alternative 2.

Alternatives 1 and 3–Action Alternatives

Direct and Indirect Effects

The occurrence will not be directly affected. It lies 50 feet from the nearest DFPZ unit. Although that unit is part of the DFPZ it would not be treated under any of the alternatives.

There would be no indirect effects to Plumas ivesia because the nearest treatment would be over 500 feet from this occurrence. Grizzly Creek flows between the occurrence and the DFPZ further isolating it from any indirect effects. The nearest known noxious weed occurrence is over 2000 feet away. That occurrence has been treated twice each year since 2006 and will continue to be treated.

Cumulative Effects

There would be no cumulative effects to the Plumas ivesia as a result of implementing either of the action alternatives.

Existing Conditions for sensitive fungi

There are no known sensitive fungi within the analysis area. Potential for Sensitive species of fungi for the Ingalls Project area were analyzed using a habitat model (Hoover and Hanlon 2008). The model was constructed to identify areas of potential habitat for fungi species. These areas were ranked according to the quality of the potential habitat (high, medium and low) and the likelihood of the Sensitive fungi species occurring there. According to the model 14 acres of medium-quality potential habitat exists in the analysis area.

Environmental Consequences for sensitive fungi

There are approximately 14 acres of medium-quality potential habitat in the project area according the PNF fungi habitat model. The model shows no high-quality potential habitat in the project area.

Alternative 2 – No Action Alternative

Effects to sensitive fungi are unlikely because the areas of potential habitat would not be affected by project activities.

Alternatives 1 and 3–Action Alternatives

Effects to sensitive fungi are unlikely because the areas of potential habitat would not be affected by project activities. The four parcels of identified sensitive fungi habitat in the analysis area are at least ½ mile away from any proposed project activity.

Summary of Determinations

It is the determination of the project botanist that Alternatives 1and 3 may affect individuals of lens-pod milk-vetch but are not likely to lead to a loss of viability or a trend toward federal listing as Threatened or Endangered for lens-pod milk-vetch. All alternatives are expected to maintain the existing plant occurrences within the project area as a result of implementing protection measures.

It is my determination that the Alternatives 1 and 3 will not affect the Plumas ivesia. All alternatives would avoid the location of the one known occurrence within the project area.

It is the determination of the project botanist that the Alternatives 1 and 3 will may affect individuals of sensitive species of fungi but are not likely to lead to a loss of viability or a trend toward federal listing as Threatened or Endangered. All alternatives would avoid the locations of known potential habitat within the project area.

Noxious Weed Risk Assessment

Introduction

This Noxious Weed Risk Assessment has been prepared to evaluate the effect of the Ingalls Project on California Department of Food and Agriculture (CDFA) listed noxious weeds and other invasive non-native plant species. This Risk Assessment documents potential effects from this project on spotted knapweed (*Centaurea maculosa*), tall whitetop (*Lepidium latifolium*), and Canada thistle (*Cirsium arvense*) in the analysis area. No other currently listed CDFA noxious weeds or other invasive non-native species are known from the project area.

Analysis Methodology

The area of analysis for noxious weed risk assessment includes the surrounding land up to 1 mile from the project boundary. Access routes to the project area were also considered in analyzing the risk of noxious weed infestation. Noxious weed surveys were conducted in the project analysis area by contract professional botanists and by Plumas National Forest botanists in 2007. Adequate noxious weed surveys have been completed within and adjacent to the project area. The earliest noxious weed records for this analysis area are from 2000. These records and any subsequent records of noxious weeds in the area were considered in this analysis.

Affected Environment/Environmental Consequences

Affected Environment

The California Department of Food and Agriculture's noxious weed list (http://www.cdfa.ca.gov) divides noxious weeds into categories A, B, and C. A-listed weeds are those for which eradication or containment is required at the state or county level. With B-listed weeds, eradication or containment is at the discretion of the County Agricultural Commissioner. C-listed weeds require eradication or containment only when found in a nursery or at the discretion of the County Agricultural Commissioner.

There is one known occurrence of the A-listed weed species spotted knapweed (Centaurea maculosa) in the analysis area. There are 25 known occurrences of the following B-listed weed species in the analysis area: tall whitetop (Lepidium latifolium) occurs in three sites, and Canada thistle (*Cirsium arvense*) in 22 sites.

Environmental Consequences

Alternative 2 –No Action

Non-project dependent weed vectors include: roads, personal woodcutting, grazing allotments, commercial timber harvest in adjacent lands, and recreational activities including camping, hiking, horseback riding, and hunting. The areas at greatest risk in this proposed project area are those located next to roads. Roads provide dispersal of exotic species via three mechanisms: providing habitat by altering conditions, making invasion more likely by stressing or removing native species, and allowing easier movement by wild or human vectors. Areas that are seasonally moist are at risk of infestation by tall whitetop. Three small sites of tall whitetop currently exist in the project area. They will continue to pose a threat if the Ingalls project is not implemented. These factors contribute to a moderate to high risk of noxious weed invasion.

Action Alternatives

There are high-priority weeds located in the analysis area. Each of these occurrences is small; the largest is 2.1 acres. They are in or near treatment units. They would be flagged and avoided; and would not be disturbed by project activities. The spotted knapweed along the access route to the project area, on county road 112, has been treated by hand pulling since 2004. Each year 2-3 plants have been found and they have been killed immediately. Tall whitetop along county road 112 has been treated annually since 2005. Continued hand pulling of spotted knapweed and tall whitetop is planned for 2011 field season. Canada thistle would be monitored as time and funding allow.

The cost to control these small infestations is relatively small. A stand-replacing wildfire could create conditions that would favor a broad scale infestation that would be difficult and expensive to control. The Ingalls project would reduce the threat of stand-replacing wildfires, and may promote the establishment of native species that have coevolved with frequent low-intensity fires in this region of the Sierra Nevada Mountains.

The project area is currently at moderate-to-high risk of noxious weed infestation. The implementation of the Ingalls project is predicted to result in a moderate-to-high potential for weed introduction and spread if all SOPs are adopted, and all road construction, reconstruction and closure is implemented. If no noxious weed SOPs are incorporated into the project it is likely that new weeds would be introduced and become established in project created suitable habitat. SOPs and the design of the Proposed Action would decrease the risk associated with habitat alteration expected as a result of the project and increased vectors as a result of project implementation. Habitat vulnerability and non-project dependent vectors would not be changed by the SOPs. However, monitoring during project implementation and post project, avoidance of known sites, and treatment of any weed populations discovered during implementation will greatly reduce the chances of spread of weeds in the project area.

The overall risk of noxious weed establishment as a result of Ingalls project implementation is moderate to high.

Cultural Resources

Introduction

Cultural objects, historic structures and buildings, and archaeological sites are the material remains of our national heritage. The Plumas National Forest is responsible for, and committed to protecting and managing these nonrenewable resources for current and future generations to understand and enjoy.

Analysis Methodology

Three phases of work were completed to understand the significant themes and extent of cultural resources within the Ingalls project area. First, research into the larger geographic history relevant to the project area was conducted to understand historic themes or events that have transpired in time and space. Next, cultural resource field surveys were conducted to identify cultural properties. Finally, the survey methodology and amount and types of cultural resources observed within the project area are discussed in a specialist report.

The entire area of potential effect was previously surveyed during several earlier projects. This includes two contracts specifically for this project (2007 and 2010) as well as work completed by Forest Service Archaeologists. Based on previous studies and the inventories conducted for this undertaking, the entire area has been adequately assessed for cultural resources. All identified cultural resources have been fully recorded and are on file at the Beckwouth Ranger District office. All known cultural resources within the Ingalls project area of potential affect were field visited and the site boundaries have been flagged.

Environmental Consequences

Effects of Alternative 2 (No Action) on Cultural Resources

With no proposed activity, there would be no effect to cultural resources.

Effects of Action Alternatives on Cultural Resources

Cultural Resource site boundaries are flagged and Standard Operating Procedures would be followed during implementation of any of the action alternatives. All artifacts and features would be avoided during project implementation therefore there would be no effect on cultural resources.

Cumulative Effects

There would be no direct or indirect effects to cultural resources from any of the alternatives therefore, there would be no cumulative effects.

Human Health and Safety

Introduction

This report examines the risk to workers and the public from proposed activities in the Ingalls project. Hand (manual), mechanical, prescribed fire treatments, and application of Borax all pose some risk to human health and safety.

Analysis Methodology

Information was reviewed for this project along with proposed mitigations such as hazard tree removal, and experience with similar projects completed in the Region and on the Forest to identify risks.

A considerable body of information for Borax has been compiled in risk assessments completed by SERA (authored by DR. Patrick Durkin, PhD) under contract to the Forest Service (SERA, 2006) and the risk assessment contained in the Herger-Feinstein Quincy Library Group Forest Recovery Act Final Supplemental EIS. Forest Service Worksheet Maker version 5.00.54 was run for application rates of 1lb acid equivalent per acre.

The pesticide risk assessment portion of this analysis consists of comparing doses that people may get from applying the pesticide (worker doses) or from being near and application site (public doses) with the U.S. Environmental Protection Agency's (U.S. EPA) established Reference Doses (RfD), a level of exposure that result in no adverse effect over a lifetime or chronic exposures. One of the primary uses of a risk assessment is risk management. Decision makers can use the risk assessment to identify those herbicides, application methods, or exposure rates that pose the greatest risks to workers and the public. To facilitate this decision-making, acceptable risk levels must be established. For each type of dose assumed for workers and the public, a hazard quotient (HQ) was computed by dividing the dose by the RfD. In general, if HQ is less than or equal to 1, the risk of effects is considered negligible. Because HQ values are based on RfDs, which are thresholds for cumulative exposure, they consider acute exposures. This aspect is discussed below in the evaluation of possible effects.

Environmental Consequences

Alternative 2 (No Action)

Alternative 2 would have no direct effects on human health because no operation of mechanical equipment, application of Borax, hand treatment, or prescribed fire would occur in relation to this project. However, if a wildfire occurs in the project area without fuel treatments, severe wildfire behavior could result in significant adverse indirect and cumulative effects to the health and safety of the public and fire suppression personnel.

Alternative 1 (Proposed Action) and Alternative 3 (Non-commercial)

Mechanical Equipment

Equipment operators can be injured in several ways. Operators can lose control of machines on steep or slippery terrain; however, such accidents are uncommon among experienced operators. Accidents can occur when operators push brush where visibility is poor, a short headwall or road-cut is encountered, or slope steepness or traction is misjudged. A machine that is out of control can roll over its operator or create hazardous flying debris. Operators can also suffer hearing damage.

Other workers are at risk of being struck by falling trees or pieces of wood or rock thrown out by the equipment, especially during tree cutting and mastication operations. Working on large machines that are slippery from oil or are otherwise hazardous also can cause injuries. Workers other than operators are also at risk of damaged hearing.

Risks to the public from use of mechanical equipment should be negligible. Injuries are possible from accidents when the equipment is being moved on public roads or in rare situations when a member of the public ignores safety warnings and enters a treatment area while equipment is operating.

Prescribed Burning

Burning creates risk of smoke and heat injury to both workers and the public. Effects on workers range from eye irritation, coughing, and shortness of breath to severe burns that can leave permanent scars or lead to mortality. In addition, chronic exposure of workers to smoke can lead to long-term adverse health effects, such as emphysema or lung cancer.

Smoke may have local, transitory effects on air quality. Sensitive members of the public may experience irritations of the eye, throat, or lung from even the low-level exposures. Risk of adverse chronic health effects on the public from smoke exposure should be lower than risks to workers, because public exposures would be much less than worker exposures.

Prescribed burns may “escape” (burn outside intend areas) and endanger the public. To reduce risks of burn “escapes” and other adverse effects, the Forest Service imposes special requirements for planning and implementing prescribed burns. All prescribed burn projects require preparation of a burn plan, which includes a burning prescription identifying requisite fuel and weather conditions for ignition, burning procedures, and safeguards. Safeguards are precautions needed to confine the burn to the prescribed area. In addition, the Forest Service has established qualification standards and training requirements for personnel involved in prescribed burning.

Hand Methods

Working with hand tools on steep slopes, and/or unfavorable site conditions is inherently hazardous. Conditions are highly variable, ranging from gentle slopes with vegetation densities to steep slopes with dense tall shrubs or trees. Extremely hot or cold ambient temperatures can occur depending on the time of year. Workers could be cut by tools, struck by falling shrubs or trees, or injured by falling onto sharp stumps or shrub stems. Risk of injuries increases with the amount of work, and are exacerbated when workers are concentrated in areas or fatigued. Injuries can result from minor cuts, sprains, bruises, and abrasions to severe injuries causing major arterial bleeding, compound bone fractures, brain concussions, or mortality.

Hand clearing of vegetation is relatively slow work, with production rates of 2-4 workdays/acre. This exposes workers to the hazards for longer periods in relation to other, more efficient methods of clearing vegetation. Risk of injuries increase as slope, vegetation density, and vegetation height increase.

Other adverse health effects associated with outdoor work in rugged terrain are possible. Examples are extreme fatigue, heat exhaustion or heat stroke, and exacerbation of chronic health conditions.

Proper supervision and effective training for safe use of hand equipment can reduce risks of worker injury. Wearing boots with non-skid soles and snag-resistant long-sleeve shirts and trousers can also reduce risks. Forest Service procedures and normal forestry worker practices involve use of these common safety practices.

Members of the public would not be expected to be at risk from the use of hand methods, because they are not likely to be sufficiently close to work.

Stump Treatment with Borax

This assessment examines the potential health effects on all groups of people who might be exposed to pesticides that are proposed in this project. Those potentially at risk fall into two groups: workers, and members of the public. Workers include applicators, supervisors, and other personnel directly involved in the application of pesticides. The public includes forest users or nearby residents who could be exposed through the drift of pesticide, through contact with vegetation, or by eating, or placing in the mouth food items or other plant materials, such as berries or shoots growing in or near the forest, by eating game or fish containing to pesticide residues, or by drinking water that contains such residues.

WORKERS- Given the low hazard quotients for both general occupational exposures as well as accidental exposures, the results imply that long-term employment applying this fungicide can be accomplished without toxic effects. All worker occupational exposures for the typical, lower and upper application rate result in an HQ of less than 1.

While accidental exposure scenarios are not the most severe one might imagine they are representative of reasonable accidental exposures. For accidental exposure the highest hazard quotient is a factor of over 1300 below the level of concern.

The hazard quotients for general occupational exposure scenarios are somewhat higher than those for the accidental exposure scenarios. Nonetheless, the upper limit of the hazard quotient is below the level of concern (an HQ of greater than 1). As previously discussed, these upper limits of exposure are constructed using the highest anticipated application rate, the highest anticipated number of acres treated per day, and the upper limit of the occupational exposure rate. If any of these conservative assumptions were modified the hazard quotients would drop substantially. The simple verbal interpretation of this quantitative characterization of risk is that even under the most conservative set of exposure assumptions, workers would not be exposed to levels that are regarded as unacceptable.

GENERAL PUBLIC – Although Borax is not applied in residential areas, it is applied in forested areas that may be used by members of the general public, however, because Borax would be applied to freshly created stumps during logging of the harvest unit, it is highly unlikely that a member of the public would be exposed to either freshly treated stumps, or water containing Borax. All short term and chronic exposure scenarios except the direct consumption of the granules from a tree stump are well below an HQ of 1.

The acute exposure scenario in which a child ingests Borax applied to tree stumps as proposed exceeds an HQ of 1 at the lower, upper, and central exposure estimates. There is no information in the available literature to estimate the amount of Borax that a child could be predicted to consume in one day. The estimated amount of Borax that a child may consume in one day is based on the amount of soil that an average child may ingest per day. For a child ingesting Borax from a tree stump, hazard quotients range from 2 to 16, with a central estimate of 4. The estimated amount of Borax that a child may consume in one day is based on the range for the amount of soil that may be consumed by children and this may not reflect the amount of Borax that a child might consume in a single event. Since the exposure estimate is highly uncertain and not based on empirical data for borate consumption, risk for this exposure scenario may be underestimated or overestimated. Relatively good estimates of lethal and sublethal doses in children are available. Documented lethal doses are in the range 505 mg B/kg/day and 765 mg B/kg/day, factors of about 11 to 135 below the estimated levels of exposure from ingesting borax from a treated stump. A nonlethal dose in children is about 184 mg B/kg/day and this dose is associated with gastrointestinal effects such as vomiting and diarrhea. The estimated levels of exposure for a child ingesting borax from a treated stump are below this nonlethal level by factors of about 4 to 32. Thus, while this exposure scenario raises concern in that the RfD is substantially exceeded, the most likely adverse effects would probably be vomiting and diarrhea.

Legal Regulatory Compliance and Consultation

The Beckwourth Ranger District operates under a diverse array of local, state and federal management guidance and policy as well as various executive orders.

Currently, the Beckwourth Ranger District is guided by the Plumas National Forest 1988 Land and Resource Management Plan (LRMP) as amended by the Herger-Feinstein Quincy Library Group (HFQLG) 1999 Final EIS and Record of Decision (ROD), the 2003 HFQLG Supplemental EIS and ROD and the 2004 Sierra Nevada Forest Plan Amendment (SNFPA) supplemental EIS and ROD.

Principle Environmental Laws

National Environmental Policy Act

The Council on Environmental Quality (CEQ) regulations for implementing the National Environmental Policy Act (NEPA) requires that federal agencies rigorously explore and objectively evaluate all reasonable alternatives and briefly discuss the reasons for eliminating any alternatives that were not developed in detail (40 Code of Federal Regulations [CFR] 1502.14).

The Ingalls Project EA meets the CEQ regulations requiring public scoping and a thorough analysis of issues, alternatives and effects.

National Forest Management Act

The National Forest Management Act (NFMA) reorganized, expanded and otherwise amended the Forest and Rangeland Renewable Resources Planning Act of 1974, which called for the management of renewable resources on national forest lands. The NFMA Act requires the Secretary of Agriculture to assess forest lands, develop a management plan for each unit of the National Forest System (NFS).

The Forest Service is complying with the provisions of this law by designing the project to meet the Standards and Guidelines of the Plumas Forest Plan and its amendments.

Endangered Species Act

The Endangered Species Act of 1973 (16 USC 1531 et seq.) requires that any action authorized by a federal agency not be likely to jeopardize the continued existence of a threatened or endangered (TE), or result in the destruction or adverse modification of habitat of such species that is determined to be critical. Section 7 of the ESA, as amended, requires the responsible federal agency to consult with the United States Fish and Wildlife Service (USFWS) and the National Marine Fisheries Service concerning TE species under their jurisdiction. It is Forest Service policy to analyze impacts to TE to ensure management activities are not be likely to jeopardize the continued existence of a TE, or result in the destruction or adverse modification of habitat of such species that is determined to be critical. This assessment is documented in a Biological Assessment (BA) and is summarized or referenced in Chapter 3.

Wildlife and Fisheries

Consultation with USFWS

Section 7 consultation with the USFWS was not required for the Ingalls project. A list of T&E species was provided by the "Federal Endangered and Threatened Species that may be affected by Projects on the Plumas National Forest", updated April 29, 2010, accessed via USFWS county list web page (http://www.fws.gov/sacramento/es/spp_lists/NFActionPage.cfm) (Appendix A of the BA/BE)was used for analysis. Based on the analysis conducted in the BA/BE, it was determined that no effects to listed TE species would occur from implementation of the Ingalls Project, therefore no consultation under Section 7 of the Endangered Species Act of 1973, as amend was required.

California Department of Fish and Game

Input specific to the Ingalls project was solicited from the Department of Fish and Game through the public scoping process. However, since no input was received, all past advice from the Department was considered during the planning of the Ingalls Project.

Botany

The latest US Fish and Wildlife Service (USFWS) species list for Plumas County, in which the project occurs, was accessed from the USFWS website on April 7, 2011 and incorporates the database update of December 1, 2009 (USDI 2009). This list fulfills the requirements to provide a current species list pursuant to Section 7(c) of the Endangered Species Act, as amended.

The only Federally Threatened plant species known to occur on the Plumas NF is *Packera layneae* (Layne's butterweed). This species grows in open rocky areas on gabbro and serpentine-derived soils that are between 650 and 3,300 feet in elevation. The Plumas NF has four occurrences, totaling approximately 12 acres. There is no suitable habitat for this species within or near the Ingalls Project area. Two additional species of federal concern that have the potential to occur on the Plumas NF are the Federally Threatened *Orcuttia tenuis* (slender Orcutt grass) and the Candidate species *Ivesia webberi* (Webber's ivesia). *Orcuttia tenuis* is limited to relatively deep vernal pools with clay soil. *Ivesia webberi* is found in open areas of sandy volcanic ash to gravelly soils in sagebrush and eastside pine. Suitable habitat for these two species within the analysis area has been surveyed by qualified botanists. No individuals of these two species were found during field surveys. Therefore, no Threatened or Endangered species occur within the project area and a Biological Assessment is not needed.

Clean Water Act

Section 208 of the Clean Water Act required the States to prepare non-point source pollution plans, which were to be certified by the State and approved by the Environmental Protection Agency (EPA). In response to this law and in coordination with the State of California Water Resources Control Board (SWRCB) and EPA, Region Five began developing Best Management

Practices (BMPs) for water quality management planning on National Forest System lands within the State of California in 1975.

The Ingalls Project meets the Clean Water Act by implementing the Best Management Practices of the Soil and Water Conservation Handbook. By using BMPs, the Ingalls Project meets this Act according to the ROD of the SNFPA (Section VII, ROD of the SNFPA).

Clean Air Act

The Clean Air Act provides the principal framework for national, state and local efforts to protect air quality. Under the Clean Air Act, the Office of Air Quality Planning and Standards is responsible for setting standards for pollutants which are considered harmful to people and the environment. The 1990 Clean Air Act is the most recent version of a law first passed in 1970.

All burning that will be done on the Ingalls Project will be in accordance with an approved smoke management plan approved by the Northern Sierra Air Quality Management District (NSAQMD). The smoke plan requires burning with wind directions that transport smoke away from communities and the amount of acres burned daily are limited. Burns are conducted during approved burn days, when atmospheric conditions favor smoke dispersion. Prescribed burning takes place in spring or fall after the first rains when fuels are relatively moist to reduce the potential for fire escape.

National Historic Preservation Act

Section 101 of the National Environmental Policy Act (NEPA) requires the federal government to preserve important historic, cultural and natural aspects of our natural heritage. To accomplish this, federal agencies utilize the Section 106 process of the National Historic Preservation Act (NHPA). This process has been codified in 36 CFR 800 Subpart B. The coordination or linkage between the Section 106 process of the NHPA and the mandate to preserve our national heritage under NEPA is well understood and is formally established in 36 CFR 800.3b and 800.8. Locally, the Plumas National Forest uses a programmatic agreement (PA) between Region 5 of the US Forest Service, the California State Historic Preservation Officer and the Advisory Council on Historic Preservation to implement the Section 106 process.

The Ingalls Project EA meets NHPA by protecting cultural resources through field survey, tribal and historical preservation society consultation and protection of sites in the Ingalls Project area. All known archaeological sites within the Ingalls Project area of potential affect, were field visited and site boundaries were flagged. As outlined in the Programmatic Agreement, protection measures will be implemented, as appropriate, for all cultural resources located within the project area. The application of the protection measures would result in the Ingalls Project having “no effect” on cultural resources and the Forest would have taken into account the effect of the project on cultural resource sites in compliance with the PA and Section 106 of the NHPA.

Executive Orders

Consultation and coordination with Indian Tribal governments, Executive Order 13175 of November 6, 2000

The following tribes were consulted during the NEPA scoping phase of the Ingalls Project on May 10, 2010:

- Washoe Tribe of California and Nevada
- Susanville Indian Rancheria
- Greenville Indian Rancheria

Indian Sacred Sites, Executive Order 13007 of May 24, 1996

Through scoping and consulting with local Native American tribes, it was determined by District Archeologist that there were no known Indian sacred sites in the Ingalls Project.

Invasive species, Executive 13112 of February 3, 1999

Executive Order 13112 created the Invasive Species Council (ISC) in order to prevent the introduction of invasive species, provide for their control and minimize the economic, ecological and human health impacts that invasive species cause. Federal agencies are required to:

- Identify actions that may affect the status of invasive species
- Use relevant programs and authorities to prevent the introduction, control and monitoring of invasive species
- Provide for native species restoration as well as their habitats
- Promote public information
- Not condone or carry out actions that may spread invasive species
- Consult with the ISC and other stakeholders as appropriate

The Ingalls Project meets the Executive Order by following the noxious weed management Standards and Guidelines in Appendix A of the ROD for SNFPA. The SNFPA guidelines direct proactive management of noxious weeds that meet with the Executive Order. District botanists carried out the intent of the Executive Order and the noxious weeds Standards and Guides by:

- Consulting with a ISC representative
- Identifying and controlling weed infestation areas
- Preventing the spread of noxious weeds through SOPs and site specific mitigation
- Educating the public regarding the presence and spread of noxious weeds

Floodplain management, Executive Order 11988 of May 24, 1977 and Protection of Wetlands, Executive Order 11990 of May 24, 1977

Executive Orders 11988 and 11990 require Federal agencies to avoid, to the extent possible, short- and long-term effects resulting from the occupancy and modification of flood plains and the modification or destruction of wetlands. These executive orders are intended to preserve the natural and beneficial values served by floodplains and wetlands.

The Ingalls Project meets these executive orders by implementing the Best Management Practices (BMP) of the Soil and Water Conservation Handbook. By using BMPs, the Ingalls Project meets the executive orders according to the ROD of the SNFPA (Section VII, ROD of the SNFPA).

Environmental Justice, Executive Order 12898 of February 11, 1994

Executive Order 12898 requires that Federal agencies make achieving environmental justice part of their mission by identifying and addressing, as appropriate, disproportionately high and adverse human health and environmental effects of their programs, policies and activities on minority and low-income populations.

Although low-income and minority populations are within the vicinity of the Ingalls Project, activities associated with the Project would not discriminate against them. Proposed activities would not adversely affect community, social, economic and health and safety factors. Public scoping was conducted in accordance with NEPA regulations to identify any potential issues or hazards associated with the Ingalls Project.

Use of off-road vehicles, Executive Order 11644 and 11989, amended May 25, 1977

It is the purpose of these orders to establish policies and provide for procedures that will ensure that the use of off-highway vehicles (OHV) on public lands will be controlled and directed so as to protect the resources of those lands, to promote the safety of all users of those lands and to minimize conflicts among the various uses of those lands.

On July 15, 2004, the Forest Service published proposed travel management regulations in the Federal Register. The final rule provides a national framework for local units to use in designating a sustainable system of roads, trails and areas for motor vehicle use. The rule's goal is to secure a wide range of recreation opportunities while ensuring the best possible care of the land.

All roads proposed to be closed in the Ingalls Project are consistent with the Plumas National Forest Motorized Travel Management Project signed November 2010 (Appendix D, Table D.3). Roads being proposed for decommissioning, closure, and/or obliteration are guided by the forest wide OHV analysis process and the Riparian Management Objectives, which set forth goals for water quality and soil compaction.

Special Area Designations

The selected alternative will need to comply with laws, regulations and policies that pertain to the following special areas:

Research Natural Areas

There are no Research Natural Areas with the Ingalls Project Area.

Inventoried Roadless Areas

There are no Inventoried Roadless Areas within the Ingalls Project Area.

Wilderness Areas

There are no Wilderness Areas within the Ingalls Project Area.

Wild and Scenic Rivers

There are no Wild and Scenic Rivers in the Ingalls Project Area.

Municipal Watersheds (FSM 2540)

There are no Municipal Watersheds in the Ingalls Project Area.

Chapter 4: Consultation and Coordination

Introduction

The US Forest Service operates under the Endangered Species Act, which requires consultation with the US Fish and Wildlife Service regarding impacts to potential endangered species from the Proposed Action and the action alternatives. Consultation is also done with federally recognized tribes to ensure that heritage resources are respected and will not be impacted by any potential project activities.

Federal, State and Local Agencies

- Regional Water Quality Control Board
- City of Portola, California
- Plumas County

Tribal Consultation

- Washoe Tribe of California and Nevada
- Greenville Rancheria
- Susanville Indian Rancheria

Appendix B: Standard Operating Procedures

The following Standard Operating Procedures (SOP) apply unless specifically allowed for in the environmental analysis.

Fire/Air Quality

Compliance with Air Quality: Comply with air quality permits issued by the Northern Sierra Air Quality Management District for all prescribed burning. A prescribed burn plan, including a mandatory smoke management plan (SMP), would be required prior to any prescribed fire. The SMP is reviewed and approved by the local Air Quality Management District office.
Smoke Management: Conduct prescribed burning in a manner that avoids excessive buildup of smoke in any particular air shed**.**
Tree Mortality: No more than 10% mortality in the residual crop trees following the underburning and no areas of mortality greater than 2 acres; Minimize mortality in visual corridors.

Watershed

Protect water quality by using BMPs, employed by the Forest Service and the State of California to prevent water quality degradation and to meet State Water Quality Objectives relating to non-point sources of pollution. In addition, use site-specific mitigation measures that relate directly to these BMPs to minimize erosion and resultant sedimentation.

Apply the Standards and Guidelines identified in the PNF LRMP Streamside Management Zone (SMZ) and SAT Guidelines (as adopted under the HFQLG EIS) relating to timber sale activities in all RHCAs. Activities in RHCAs would improve or maintain the structure and function of the RHCA and fish and wildlife habitat.

Defining Riparian Habitat Conservation Areas, Streamside Management Zones and Sensitive Areas

Fish-bearing Streams: For perennial fish-bearing streams the RHCA consists of the stream and the area on either side of the stream extending from the edges of the active stream channel to the top of the inner gorge, or to the outer edges of the 100-year floodplain, or to the outer edges of riparian vegetation, or to a distance equal to the height of two site-potential trees, or 300’ horizontal distance, whichever is greatest.
Perennial Non-fish-bearing Streams: For perennial non-fish-bearing streams the RHCA consists of the stream and the area on either side of the stream extending from the edges of the active stream channel to the top of the inner gorge or to the outer edges of the 100-year floodplain, or to the outer edges of riparian vegetation, or to a distance equal to the height of one site-potential tree, or 150 feet, whichever is greatest.

Lakes: For natural lakes the RHCA consists of the body of water and the area to the outer edges of the riparian vegetation, or to the extent of moderately and highly unstable areas, or to a distance equal to the height of two site-potential trees, or 300 feet horizontal distance, whichever is greatest.

Ephemeral or Intermittent Streams, Wetlands Less Than One Acre, Landslides and Landslide-prone Areas: Intermittent and ephemeral streams showing annual scour and deposition, and definable stream channel wetlands, use RHCA widths of a minimum of 100 feet in width (horizontal distance) or the height of one site potential tree, whichever is greater.

Ponds, Reservoirs, and Wetlands Greater Than One Acre: Extend RHCAs around wetlands and perennial non fish-bearing streams to the outer edges of the riparian vegetation, or to the extent of seasonally saturated soil, or to the extent of moderately and highly unstable areas, or a 150 feet horizontal distance, whichever is greatest.

Streamside Management Zones: Employ streamside management zone (SMZ) widths that are 50 feet for those stream segments that do not display annual scour and deposition and are not classified as RHCAs.

Treatments in RHCAs & SMZs

Ground Based Harvesting Soil Conditions: See the section in these SOPs on Soil Protection Measures.

Equipment Use in RHCAs/SMZs: Equipment use within RHCAs and SMZs is restricted by the equipment exclusion zones. Equipment exclusion zone widths, measured on each side of the stream from the edge of the active channel, vary depending upon the RHCA and SMZ widths presented above: for 150 ft wide RHCA buffers, the equipment exclusion zone width is 50 ft on each side of the channel; for 300 ft wide RHCA buffers, the equipment exclusion zone width is 100 ft on each side of the channel; and for SMZs, the equipment exclusion zone width is 25 ft on each side of the channel. For seeps, springs, and meadows, the equipment exclusion zone width is 25 ft, measured from the wet perimeter of the soil of facultative wetland species edge, whichever is furthest. Equipment must be excluded from all sensitive areas, unless specifically allowed for in the environmental document. Machinery can work adjacent and reach into the exclusion zone with the extendable boom. Minimize the number of crossings. Crossings would be back-bladed after use, as necessary, to restore the natural relief and reduce erosion.

Slope Restrictions: Mechanical equipment would be restricted to slopes up to 25%.

Bank Stability: Remove no trees adjacent to channels that provide bank stability and/or contribute to channel integrity (except for hazard trees). Along perennial fish-bearing streams where hardwoods are < 12" and insufficient to provide shade to the stream channel conifers would be left to provide shade.

Landing Location: Minimize landing location in RHCAs. Landings would generally not be within 100 feet of the stream course. District hydrologist or soil scientist would approve, on a site-specific basis landings that need to be closer than 100 feet of a stream course.

Skid Trail Location: Skid trails would be allowed within equipment exclusion zones on a case-by-case basis with permission of the District's hydrologist, geologist or soil scientist and would generally only be allowed for crossing stream courses. Skid trails would be perpendicular to the stream course within 50 feet of the stream and spacing of skids would be no closer than 120 feet. Throughout RHCAs and SMZs, skid trails would be restricted to less than 25% slope. Do not locate skid trails parallel to the bottom of swales. Treat swales as stream courses, crossing at right angles and skidding away from these features.

Restoring Landings: Where specified by the District's physical scientist, existing and activity related disruptions in landings would be restored to their natural contour. This would occur during subsoiling operations. These landings would be tilled, seeded, mulched after use and available slash would be spread out across landing to improve infiltration and minimize erosion upon site visit. Mulch and then subsoil landings and other disturbances within 200 feet of stream channels. Areas within 50' of the meadow edges would not be subsoiled. All project subsoiling activities are to be approved by the District physical scientist prior to subsoiling. Reference: BMP 1-12

Restoring Skid Trails & Temporary Roads: Where specified by the District's physical scientist, existing and activity related disruptions in skid trails and temporary roads would be restored to their natural contour. This would occur during subsoiling operations. Areas within 50' of the meadow edges would not be subsoiled.

Slash Near Stream Courses: Remove any slash generated by project activities from stream courses as soon as practicable, not exceeding 48 hours.

Burn Pile Locations: Locate burn piles above the "green line" or at least 25' away from channels having evident scour and deposition, whichever is greater. Burn the piles prior to underburning. Allow backing fire to creep into RHCAs if fuels naturally carry the fire.

Hazard Tree Removal in RHCAs and SMZs: With case-by-case permission of the project Sale or Contract Administrator, hazard trees may be hand-felled and left in place or removed from RHCAs and SMZs in a manner that minimizes disturbance to the RHCA or SMZ. Mechanical entry would be subject to the equipment exclusion zones described above.

Large Woody Debris Retention: Retain at least 90% of large woody debris in channels and leave 50-75% of the ground unburned within the interior 50' of RHCAs. Within these core areas, ensure that burned areas appear intermittent, not concentrated.

Soil Protection Measures

Ground Cover: To control the surface erosion, the 1988 Plumas National Forest Land and Resource Management Plan suggests retaining a minimum of 40% ground cover on soils with a low erosion hazard rating. The minimum ground cover increases to 50%, 60% and 70% for soils with an erosion hazard rating of moderate, high and very high, respectively. These suggested guidelines are adopted as the minimum ground cover standard. If ground cover standards are not met, implement mitigation methods such as leaving chips on site to ensure standards would be met. In addition, retain 5 tons/acre of down woody debris less than 15" in diameter.

Ground Based Harvesting: Conduct ground based harvest operations only when the upper 8" of the soil is essentially dry, or the ground is frozen to a depth of 5", or snow depth is at least 18" or is compacted by equipment to 8". For this measure, soil is defined as "dry" when no portion of the top 8" can be molded by hand compression and hold that shape when the hand is tapped.

Slope Restrictions: Allow low ground pressure (under 8.0 psi when "unloaded") excavators to work on slopes up to 45% to pile excess fuels. All other mechanical equipment would be restricted to slopes that are equal to or less than 35 percent.

Skid Trails: Restrict skidding equipment to designated skid trails, unless, through consultation with the District's hydrologist, geologist or soil scientist, it is determined that departure from skid trails would not likely impair the soil or the operator is using low ground pressure (under 8.0 psi) harvesting equipment to travel off designated skid trails to bring logs to trails. Generally use skid trail spacing averaging120', center to center, when trails are parallel and generally perpendicular to the stream. Reusing existing skid trails, with spacing closer than prescribed, is acceptable.

Subsoiling Landings & Skid Trails: Based upon the soil type, existing landings and skid trails used by the project and newly created skid trails with compacted soil, would be subsoiled using a wingtip subsoiling implement and displaced soil would be leveled and slash scattered. In general, constructed skid trails experiencing *three or more* passes with equipment, would be subsoiled to a minimum depth of 24", water-barred and blocked. However, all project subsoiling activities are to be approved by the District physical scientist prior to subsoiling. Subsoiling skid trails within harvest units on coarse textured soils (USDA texture classes: sands, loamy coarse sands; and coarse sandy loams with less than 5% clay content) that have developed from granitic parent material would generally not be recommended.

Subsoiling Specifications: Where specified by the District's physical scientist, subsoil skid trails, landings, temporary roads, and non-system roads within the project area through the full depth of compaction to restore soil porosity. Selected landings and terminating skid trails would be subsoiled with a winged subsoiler or other equipment capable of lifting and fracturing compacted soil without mixing the soil horizons to a depth of at least 24". The subsoiler would be lifted where substantial root and bole damage to larger trees would occur from subsoiling. Skids with slope over 25% may not be approved for subsoiling but would be frequently water barred per project BMPs. Areas within 50' of ephemeral draws, swales, connected drainages and meadow edges would not be subsoiled. Subsoiling would not occur on shallow soils where the displacement of rocks disrupts soil horizons or where there are concerns about the spread of root disease, or damage to tree roots. When landings and temporary roads are planned for subsoiling, recovery of topsoil displaced during construction would be considered. Block vehicle access to temporary roads and install water-bars prior to subsoiling them.

Transportation

Stream Crossings: Design all new stream crossings to accommodate a 100-year flood and provide fish passage as necessary.

Restore Temporary Roads: Restore temporary roads after use. Design and obliterate temporary stream crossings to protect water quality and adjacent riparian vegetation (see "Watershed" section for additional procedures for protecting riparian vegetation).

Water Bars: Stabilize and strategically place water bars on temporary roads where drainage control issues are evident or expected.

Road Barricades: After use, barricade temporary roads to discourage vehicle traffic, using available natural materials such as rocks, logs, root wads and earth, to appear somewhat natural, have low installation costs and require little to no maintenance.

Dust Abatement: Abate dust from logging traffic with water selected from water drafting sites that have suitable stream flow and access. When water is scarce, use alternative sources such as chlorite, sulfonate or other dust abatement materials.

Drafting Sites: Estimate maximum drawdown volumes prior to using the draft site. Maintain minimum pool levels during drafting using measurements such as staff gauges, stadia rods, tape measures, etc. Construct water-drafting sites so that oil, diesel fuel, or other spilled pollutants would not enter the stream. Maintain stream bank stability and minimize sedimentation by constructing and maintaining back down ramps. Rocking, chipping, mulching, or other effective methods are acceptable in achieving this objective. Suction strainers must contain screen openings with less than 2mm holes and meet the specifications outlined in FSM 5161. The suction strainer shall be inserted close to the substrate in the deepest water available; the suction strainer shall be placed in a bucket to avoid substrate and amphibian disturbance.

Silviculture

Borax Application: Treat all stumps > 14" diameter with a borate compound for the control of *Annosus* root disease. Apply borate compound to all pine and true fir cut stumps within Recreation Areas, within 4 hours of cutting the trees.

Genetic Stock Protection: Protect trees identified or trees being tested as genetically superior or resistant to blister rust or dwarf mistletoe.

Botany

Protection for Plant Species: Protect known Threatened, Endangered, Sensitive and Special Interest plant species according to Plumas National Forest current interim management prescriptions for specific species. If additional protected plant species are found during the life of the project, conduct an assessment and apply appropriate management prescriptions.

Noxious Weed Management

The SOPs are based on the priorities established in FSM 2081.2 which states "where funds and other resources do not permit undertaking all desired measures, address and schedule noxious weed prevention and control in the following order:

- First Priority: Prevent the introduction of new invaders,
- Second Priority: Conduct early treatment of new infestations
- Third Priority: Contain and control established infestations.

1. **Prevention/Cleaning**: Require all off-road equipment and vehicles (Forest Service and contracted) used for project implementation to be weed-free. Clean all equipment and vehicles of all attached mud, dirt and plant parts at a vehicle washing station or steam cleaning facility before the equipment and vehicles enter the project area. Cleaning is not required for vehicles that would stay on the roadway. In addition, clean all off-road equipment prior to leaving areas infested with noxious weeds.
2. **Prevention/Road Construction, Reconstruction and Maintenance:** All earth-moving equipment, gravel, fill or other materials need to be weed free. Use onsite sand, gravel, rock, or organic matter where possible.
3. **Prevention/Revegetation:** Use weed-free equipment, mulches and seed sources. Avoid seeding in areas where revegetation would occur naturally, unless noxious weeds are a concern. Save topsoil from disturbance and put it back to use in onsite revegetation, unless contaminated with noxious weeds. All activities that require seeding or planting would need to use only locally collected native seed sources. Collect plant and seed material as close to the project area as possible, from within the same watershed and at a similar elevation whenever possible. Avoid persistent non-natives such as timothy, orchard grass, or ryegrass. This would implement the USFS Region 5 policy that directs the use of native plant material for revegetation and restoration for maintaining "the overall national goal of conserving the biodiversity, health, productivity and sustainable use of forest, rangeland and aquatic ecosystems".
4. **Prevention/Staging Areas:** Do not stage equipment, materials, or crews in noxious weed infested areas where there is a risk of spread to areas of low infestation.
5. **Small Infestations:** Small infestations identified during project implementation would be evaluated and hand treated or "flagged and avoided" according to the species present and project constraints. Larger infestations identified after implementation, should be isolated and avoided with equipment (and equipment washed as in # 1 above).

Wildlife

Wildlife Limited Operating Periods: Unless determined to be unnecessary following pre-implementation surveys, limited operating periods (LOPs) to protect key wildlife species listed in the HFQLG FEIS (page 2-8, Table 2.3), 2004 SNFPA ROD (pages 54-62) and the Biological Evaluation/Biological Assessment would apply.

New Wildlife Findings: Where subsequent surveys identify occupied threatened, endangered, or sensitive species habitat, establish PACs, den site buffers, or other protections as described in the SNFPA EIS and HFQLG EIS. Include protections for any additional sensitive species identified in the BE/BA. In the event of a verified TES species occurrence after project award, the appropriate LOPs would apply. Other mitigations may take place as agreed upon by the Sale Administrator and District Wildlife Biologist.

Known Populations: In areas of known populations of TES amphibians, apply direction from the HFQLG FEIS/ROD and the SNFPA ROD. Apply additional protection measures as follows: do not burn slash piles within RHCAs during the LOP and when burned, assure that 1) no fuel is dumped on the pile and fusees or a single torch is used to light the pile and 2) light piles from a single location rather than multiple locations, allowing sheltering amphibians to escape.

Down wood and snags

Down wood and snag retention would follow the Standards and Guides in Table 2 of the 2004 SNFPA ROD.

Down Wood: Within westside vegetation types, generally retain an average of 10-15 tons (> 15' diameter) of large down wood per acre over the treatment unit. Within eastside vegetation types, an average of 3 large down logs would generally be retained per acre. In areas considered deficient in large woody debris, wherever possible leave cull logs at the stump rather than being skidded to the landing. The Sale Administrator and the District Wildlife Biologist would agree upon the location and amount.

Snags: Snag retention levels would be determined on an individual, project basis; however, they would consider the guidelines set forth in the Standards and Guides (USFS 2004). The Guidelines state that projects would retain 4 of the largest snags per acre in westside mixed conifer and ponderosa pine types; 6 of the largest snags per acre in the red fir forest type; 3 of the largest snags per acre in the eastside and eastside pine types; and 4 of the largest snags in westside hardwood ecosystems. Wherever possible, use snags larger than 15"dbh to meet these guidelines.

Cultural Resources

The proposed project has the potential to affect cultural resources. As outlined in the Programmatic Agreement, the following protection measures would be implemented, as appropriate, for all cultural resources located within the project area. The application of the following protection measures would result in the project having "no effect" on cultural resources and the Forest would have taken into account the effect of the project on cultural resource sites in compliance with the Programmatic Agreement and Section 106 of the NHPA.

If any unrecorded cultural resources (artifacts, features, or sites) are encountered as a result of project operations, all activities in the vicinity of such finds would immediately cease pending an examination by the District Archaeologist.

- At a minimum, cultural resource sites shall be excluded from areas where activities associated with the project would occur.
  1. All proposed activities, facilities, improvements and disturbances shall avoid cultural resource sites. Avoidance means that no activities associated with the project that may affect cultural resource sites shall occur within a site's boundaries, including any defined buffer zones. Portions of the project may need to be modified, redesigned, or eliminated to properly avoid cultural resource sites.
  2. All known cultural resource sites within the area of potential effect shall be clearly delineated prior to implementing any associated activities that have the potential to affect cultural resource sites.
  3. Buffer zones may be established to ensure added protection where the Forest or District Archaeologist determines that they are necessary. The use of buffer zones in conjunction with other avoidance measures are particularly applicable where setting contributes to the property's eligibility under 36 CFR 60.4, or where it may be an important attribute of some types of cultural resource sites (e.g., historic buildings or structures; historic or cultural properties important to Native Americans). The size of buffer zones needs to be determined by the Forest or District Archaeologist on a case-by-case basis.
  4. When any changes in proposed activities are necessary to avoid cultural resource sites, e.g., project modifications, these changes shall be completed prior to initiating any activities.
  5. Monitoring during project implementation, in conjunction with other measures, may be used to enhance the effectiveness of protection measures.
  6. Upon approval of the Forest or District Archaeologist, low intensity underburning may be allowed over selected prehistoric sites as long as fuel loads are relatively light.
  7. The Forest or District Archaeologist may approve the use of mechanical equipment to remove brush or woody material from within specifically identified areas within site boundaries under prescribed measures designed to prevent or minimize effects. Vegetative or other protective padding may be used in conjunction with the Archaeologist's authorization of certain equipment types within site boundaries.
  8. Upon approval of the Forest or District Archaeologist, existing breaches within linear sites may be designated on the ground and reused for project activities.
  9. Roads and trails that currently overlie historic linear sites may continue to be used as transportation routes without notification. However, if there are activities that would change the morphology of the existing road or trail (that is overlaying a historic linear site), these activities need to be reviewed by the Forest or District Archaeologist.
  10. Roads proposed to be restored that extend through archaeological sites would need to be blocked instead of sub-soiled.
  11. Vegetation may be removed within sites using hand tools, so long as ground disturbance is minimized and features are avoided. The removed vegetation shall not

be piled within site boundaries unless the location has been specifically approved by the Forest or District Archaeologist.

Visual Quality Management (Immediate Foreground of Visual Corridors)

Landing & Skid Trail Locations: To the extent feasible, locate landings and primary skid trails away from the immediate foreground of Sensitivity Level I and II travel corridors. Limit size of landings so that they are not visually evident from the sensitive travel routes following completion of treatment activities.
Stump Heights: Minimize stump heights in both mechanical and hand thinning units adjacent to sensitive travel corridors, typically resulting in stumps 6" or less in height within 300' of the travel corridor.
Tree Marking: During tree marking, open and enhance views of residual old growth trees near the visual corridor where possible.
Burn Piles & Underburning: Target consumption of burn piles to 95% or greater. Target underburn mortality levels of 5% or less.

Implementation

NEPA and Implementation: Within the project contract area, allow minor adjustments in boundaries of units if compatible with Forest Plan direction, the desired conditions and anticipated environmental effects disclosed by the project's NEPA document.

Range

Maintenance of Range Improvements: Range improvements would be protected from damage caused by the project. Contracts and burn plans would display where range improvements are located and include provisions to rebuild to standard any range improvements, which are damaged by the contractor. Range improvements for each allotment are listed in Part 3 of the permittee's Term Grazing Permit.
Coordination with Range Conservationist: The Forest Service Contract Administrator and the Forest Service Prescribed Burn Manager should coordinate with the Forest Service Range Conservationist early each spring to discuss the portions of the project that would be implemented that year. The Forest Service Range Conservationist should discuss those project activities in the Annual Operating Instructions meeting with the permittee prior to the District Ranger's approval of that year's Annual Operating Instructions.

Appendix C: Cumulative Effects Analysis displaying present and future foreseeable projects on the Ingalls Project area.

Introduction

According to the Council on Environmental Quality (CEQ) NEPA regulations, "cumulative impact" is the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such actions (40 CFR § 1508.7).

In order to understand the contribution of past actions to the cumulative effects of the Proposed Action and alternatives, this analysis, with the exception of hydrology relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects. This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the Proposed Action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions may ignore the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, "agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions." For these reasons, the analysis of past actions in this section is based on current environmental conditions.

Most of the specialists use the aforementioned cumulative effects analysis rationale, with the exception of watershed, where past actions over a 30-year period are used as an input to the Equivalent Roaded Acre analysis model. A list of past treatment types, year and acres are provided in a separate table.

The cumulative effects analysis areas vary depending on the specialist doing the analysis (Appendix C, Figure C.1). Botany, Soils, Cultural Resources, Fuels and Forest Vegetation use the Project area. Hydrology uses the combined Watershed boundaries. Wildlife goes out two PACs away from the project area. Noxious weeds are analyzed using a one-mile buffer around the project area.

Additionally, the potential for Defensible Fuel Profile Zone maintenance would not be analyzed in the present and future foreseeable cumulative effects analysis. There are no current plans to maintain the DFPZ, therefore any discussion of such activities would be qualitative, in other words, we have no knowledge of which acres or types of maintenance treatment would need to be performed. Moreover, the Forest has no idea how budgets would look in the future and whether we would be able to afford to maintain the DFPZ network. Any future work would require a new decision, since this environmental analysis only covers one entry.

Ingalls Project area (17,866 acres) —The boundary was used to assess impacts that extend beyond areas of actual treatment but do not extend outside the assessment area. The effects considered at this level include snags, down wood levels, seral stage distribution, stream condition, road density and condition, threatened and endangered species, archeological sites, noxious weed presence and fuel loading.

Extended Area —The boundary is used to assess impacts at the landscape scale and varies by the resource being analyzed (Figure 9 of the Ingalls EA). These projects are adjacent to the Project Area, falling outside the project area. The typical effects considered at this level are the amount and distribution of wildlife habitat, watershed and fishery condition, the potential for large fires and noxious weed spread. Acreages in this portion of the table reflect the combined geographic boundary between the various specialists.

Table C.1 is a compilation of the present and future-foreseeable actions that may be occurring within the largest combined extent of all of the cumulative effects analysis areas combined (Appendix C, Table C.1).

Table C 1. Present and future foreseeable projects within the Ingalls Project area and extended boundary. The extended boundary is the largest combined extent of all the cumulative effects analysis area.

Project Name	Year	Acres	Treatment Type	Misc
Ingalls Project area				
Present and Future-Foreseeable Projects				
Grizzly Valley Allotment	On-going		Active range allotment	
Grizzly Valley Community Allotment	On-going		Active range allotment	
Chase Allotment	On-going		Active range allotment	
Great Gray Owl Treatment Unit		146 acres	Improve habitat for great gray owl	
Fuelwood Gathering	2009	Entire District	153 commercial woodcutting permits for 1,228 cords of wood. 983 personal woodwoodcutting permits for 3,051 cords of wood.	No Hardwood Removal. Typically cord wood consists of down logs within the forest, along forest roads, and within cull decks created by past logging

				operations, or as standing snags.
Christmas Tree Cutting Program	2009	Entire District	5,443 permits	This consists of the trees ≤ 6 inches in diameter (measured at the ground) being removed generally along or within a short distance from open roads.
Lightening Tree Campground			campground	
Recreation				Dispersed camping, hunting, fishing, hiking, mining and OHV use.
Lake Davis Trail Phase 2	2011-2012	4.7 miles	Trail segment starting at Lightening tree campground to	
Red Clover Poco Watershed Project	2011-2012		Maintenance and road work.	
Red Clover Poco Pond and Plug Repair	2011		Stream channel repair	
Red Clover Prop 50 watershed restoration work	2011		Stream channel stabilization	
Blakeless underburn	2011	135 acres	Underburn	
Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement	2010	0.58 miles	Route addition: 12M07 13M36	
Extended Boundary				
Present and Future Foreseeable Projects				
Grizz Project EA	Not under contract	359 acres		
Walker Timber Sale (Grizz Project EA)	Under Contract 2010	684 acres	Mechanical Thinning	
Grizz Stewardship (Grizz Project EA)	Under Contract 2010	572 acres	Mechanical Thin, Masticate/Grapple Pile	
Freeman Project EIS	Not under contract	489 acres		
Freeman Timber Sales (Decision 2006, Freeman Project EIS)	Started 2006, not all implemented	256 acres	DFPZ, Area Thin and Group Selection	
Freeman Stewardship	2010 and 2011	423 acres	DFPZ and Area Thin

Keddie Ridge Hazardous Fuels Reduction Project

Final Environmental Impact Statement

Mt. Hough Ranger District, Plumas National Forest

Plumas County, California

R5-MB-236a

Lead Agency:	**USDA Forest Service**
Responsible Official:	**Alice B. Carlton, Forest Supervisor** **P.O. Box 1150** **159 Lawrence Street, Quincy, CA 95971**
For Information Contact:	**Katherine Carpenter, Project Leader** **39696 Highway 70, Quincy, CA 95971** **(530) 283-7619**

Abstract: The *Keddie Ridge Hazardous Fuels Reduction Project Final Environmental Impact Statement* documents the analysis of the proposed action (alternative A), the no action alternative (alternative B), and three other action alternatives for modifying fire behavior, improving forest and watershed health, protecting and enhancing habitat for sensitive plants and wildlife, and reducing the spread and introduction of noxious weeds. To meet the purpose and need the following treatments have been proposed: Defensible Fuel Profile Zones, Area Thinning, Group Selection, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, and noxious weed treatments in the Indian Valley area. The preferred alternative, alternative A (proposed action) and collaboration alternative, is planned utilizing the 2004 Sierra Nevada Forest Plan Amendment Record of Decision (SNFPA ROD), incorporating ideas and recommendations from interested parties, and includes ideas from the General Technical Report PSW–GTR-220 (USDA 2009). Within the 103,000 acre project area, alternative A proposes to construct 5,175 acres of Defensible Fuel Profile Zones (DFPZs); implement 494 acres of area thinning (AT) outside of DFPZs, where 34 acres of area thinning treatments would occur within a bald eagle territory; construct 284 acres of group selection (GS) within DFPZ and AT units; hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat, 76 acres of Constance's rock cress habitat, and 12 acres within a bald eagle territory; and treat 107 acres of noxious weed infestations using a combination of herbicide applications of aminopyralid or glyphosate, hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. Alternative B proposes no action. Alternative C (non-commercial funding alternative) is required in all projects with purpose and needs that include fuels reduction and excludes any activities other than fuels reduction to meet the proposed purposes and needs. Alternative C proposes 5,431 acres of DFPZ construction and 522 acres of AT outside of DFPZs, while retaining all live trees greater than or equal to

12 inches diameter at breast height (DBH) in both DFPZs and AT units. Alternative D (2001 SNFPA ROD consistent alternative) was suggested for analysis during the scoping process; this alternative follows the direction and standards and guidelines in the 2001 SNFPA ROD. Alternative D would construct 4,976 acres of DFPZ; construct 467 acres of AT outside of DFPZ units, where 34 acres of area thinning treatments would occur within a bald eagle territory; hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat, 76 acres of Constance's rock cress habitat, and 12 acres within a bald eagle territory; and treat 107 acres of noxious weed infestations using a combination of herbicide applications of aminopyralid or glyphosate, hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. Alternative E (2004 SNFPA ROD consistent alternative) was also requested for analysis during scoping and follows the direction and standards and guidelines in the 2004 SFNPA ROD. Alternative E would construct 5,112 acres of DFPZs; construct 513 acres of AT outside of DFPZ units; construct 328 acres of GS within DFPZ and AT units, where 34 acres of area thinning treatments would occur within a bald eagle territory; hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat, 76 acres of Constance's rock cress habitat, and 12 acres within a bald eagle territory; and treat 89 acres of noxious weed infestations using a combination of hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. No herbicide use is proposed under alternative E.

Objections will only be accepted from those who have previously submitted written comments specific to the project during scoping or other opportunity for public comment. Written, facsimile, hand-delivered, and electronic objections will be accepted for 30 calendar days following publication of a legal notice in the *Feather River Bulletin* (anticipated July 13, 2011). The publication date in the newspaper of record is the exclusive means for calculating the objection period for this proposal. Those wishing to object should not rely on dates or timeframe information provided by any other source. It is the responsibility of persons providing objections to submit them by the close of the objection period. Written objections must be submitted to: Randy Moore, Reviewing Official, USDA Forest Service, Regional Office R5, 1323 Club Drive, Vallejo, CA, or via facsimile to (707) 562-9229. The office business hours for those submitting hand-delivered objections are: 8:00 a.m. to 4:00 p.m., Monday through Friday, excluding holidays. Electronic objections must be submitted in a format such as an email message, plain text (.txt), rich text format (.rtf), portable document format (.pdf), or Word (.doc) to the following email address: appeals-pacificsouthwest-regional-office@fs.fed.us.

An objection must include: objector's name, address and phone number; signature or other verification of authorship upon request (scanned signature for electronic mail is acceptable); identification of the lead objector if multiple names are listed; the name of the proposed project; name and title of the Responsible Official, and name of the National Forest and/or Ranger District on which the proposed project will be implemented. It is the objector's responsibility to provide specific issues related to the project and to suggest remedies which would resolve the objection. Incorporation of documents by reference is not allowed.

Summary

The Plumas National Forest (PNF) proposes to implement the Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project) in order to modify fire behavior, improve forest and watershed health, protect and enhance habitat for sensitive plants and wildlife, and reduce the spread and introduction of noxious weeds through the following activities: Defensible Fuel Profile Zones, Area Thinning, Group Selection, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, and noxious weed treatments. The area affected by the proposal is located west of Canyon Dam, east of Eisenheimer Peak, south of Keddie Peak, and north of the Greenville Wye. The Keddie Ridge Project boundary encompasses all or portions of T. 25 N., R. 9 E., sec. 1-4, 8-12; T. 25 N., R. 10 E., sec. 1-6, 8-16, 22-24; T. 25 N., R. 11 E., sec. 5-8, 17-19; T. 26 N., R. 8 E., sec. 1, 2, T. 26 N., R. 9 E., sec. 1-17, 20-29, 32-36, T. 26 N., R. 10 E., sec. 1-36; T. 26 N., R. 11 E., sec. 2-10, 15-20, 30-32; T. 27 N., R. 8 E., sec. 1, 12, 14-15, 26-27, 34-36; T. 27 N., R 9 E., sec. 5-11, 13-36; T. 27 N., R. 10 E., sec. 2-5, 8-10, 14-36; T. 27 N., R. 11 E., sec. 27, 28, 31-34; T. 28 N., R. 10 E., 33-35, MDBM.

The Mt. Hough Ranger District has designed the project proposal to move the landscape from current toward desired conditions. There is a need for fire behavior to be modified in specific stands in order to reduce high fuel loading and resulting increased risks to people, structures, and resources. There is a need for forest health to be improved because current high stand densities in the Keddie Ridge Project area are leading to mortality from drought, insects, and fire. Overcrowded stands and high fuel loads reduce the quality of the habitat for three Region 5 Forest Service sensitive plant and wildlife species (clustered lady's-slipper orchid, Constance's rock cress, and bald eagle) and increase the risk of high severity, stand-replacing wildfire. There is a need to improve watershed health. Improperly constructed or unmaintained roads may restrict aquatic organism passage and transport sediment to streams and riparian areas, thus degrading water quality and aquatic habitat. The presence of highly invasive noxious weeds, including Canada thistle, Scotch broom, medusahead, yellow starthistle, and hoary cress, greatly increases the need for control measures to reduce the risk of weed introduction, establishment, and spread.

The desired conditions for fuels and forest health include an uneven-aged, multistoried, fire-resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of crown fire. This forest structure has a lower probability of crown fire initiation and spread under 90th percentile weather conditions. The desired condition within clustered lady's slipper sites is a fire-resilient forest with sufficient canopy cover that allows for filtered light conditions on the forest floor; a diversity of plants in the understory; adequate soil moisture and duff levels; and the maintenance of soil mycorrhizal (fungal) relationships. The desired condition for Constance's rock cress is a habitat characterized by serpentine soils, open tree canopy, and reduced levels of litter and duff; these conditions promote the expansion of individuals into sites that are currently unsuitable. The desired condition for bald eagles is to provide uneven-age forest structure composed of ponderosa and sugar pine greater than 38 inches DBH with overstory canopy cover of 40-60 percent. National Forest System (NFS) roads should ensure safe travel for forest users, and provide a transportation system that is adequate for all resource management needs. The desired condition for noxious weeds is to prevent the introduction and

establishment of new weeds and to contain and control established infestations so that high priority noxious weed species are reduced or eliminated.

The proposed action is designed to meet the standards and guidelines for land management activities described in the Plumas National Forest Land and Resource Management Plan (PNF LRMP) (USDA 1988), as amended by the Herger-Feinstein Quincy Library Group (HFQLG) Final Supplemental Environmental Impact Statement (FSEIS) and Record of Decision (ROD) (USDA 1999a, 1999b, 2003a, 2003b), and the Sierra Nevada Forest Plan Amendment (SNFPA) FSEIS and ROD (USDA 2004a, 2004b).

The Keddie Ridge Project was originally scoped in December 2006 and was being planned under authorization of the Healthy Forest Restoration Act (HFRA) (H.R. 1904; Public Law 108-148; 36 CFR §218 – Predecisional Administrative Review Process). At the time, the direction for HFRA projects was to use The Healthy Forests Initiative and Healthy Forests Restoration Act Interim Field Guide (USDA Forest Service and DOI Bureau of Land Management, FS-799, February 2004). The HFRA field guide included a decision diagram that helped determine whether a project meets the definition of “authorized” or “covered” by the HFRA. It was difficult to discern from this field guide and the associated decision models if HFRA was the correct authority to use. Portions of the Keddie Ridge Project overlap with Wildland Urban Interfaces (WUIs), the project is within a municipal watershed, and there are no areas of blowdown, wind throw, or damage by ice storms. Originally portions of the project did not qualify for HFRA authority.

The 2008 Consolidated Appropriations Act extended the HFQLG Pilot project to September 30, 2012. It also applied some portions of the Healthy Forest Restoration Act (Sections 104-106) to HFQLG projects. These sections relate to environmental analysis, public notice, comment and objection processes, and judicial review. In March 2009, the Omnibus Appropriations Act amended this, clarifying that Section 106 of the Healthy Forest Restoration Act (related to expedited judicial review) shall apply to all HFQLG projects, while Sections 104 and 105 (related to environmental analysis and objection processes) may be applied to HFQLG projects.

Individuals and organizations that expressed interest during previous scoping efforts (December 2006) were contacted to schedule collaboration meetings. Twelve individuals and organizations continued to express interest in the Keddie Ridge Project. Meetings were held from July 31 through September 1, 2009 and included the following organizations: Plumas County Fire Safe Council, Plumas County Board of Supervisors, Plumas County Horseman’s Association, Sierra Access Coalition, and Sierra Forest Legacy. Collaboration efforts continued with the Quincy Library Group (QLG), Sierra Forest Legacy, and local industry groups such as Sierra Pacific Industries, American Forest Resource Council, and California Forestry Association through April 2010.

An open house was held September 15, 2009 at the Mt. Hough Ranger District and nine individuals attended.

A Notice of Intent to prepare an Environmental Impact Statement was published in the Federal Register on April 1, 2010. Thirteen scoping letters were received.

A second open house was held June 16, 2010 at the Greenville Town Hall and seven individuals attended.

The Forest Service hosted a public field trip for all interested parties on May 26, 2010 and three individuals attended.

The Forest Service initiated an official 45 day comment period once the Notice of Availability was published in the Federal Register on February 4, 2011. A comment period notice was also published in the *Feather River Bulletin* on the following Wednesday, February 9, 2011. Ten comments were received from three agencies and seven organizations. A response to comments can be found in appendix G of this EIS. A compilation of comments received during the comment period is located in the project record at Mt. Hough Ranger District in Quincy, CA.

There were no significant issues that led the agency to develop alternatives to the proposed action. The three action alternatives, in addition to the proposed action, are required by court order or were requested during scoping.

Major conclusions include:

- Alternative A provides about 189 direct and indirect jobs and approximately $6.8 in employee related income. However, alternative A has a potential value to the US government 11 percent less than alternative E.
- Large woody debris guidelines would be met in areas proposed for treatment.
- Alternative A treatment activities would not cause any subwatersheds to exceed the Threshold of Concern.
- Alternative A may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for the mountain yellow-legged frog, bald eagle, California spotted owl, Northern goshawk, American marten, or Pacific fisher.
- Alternative A would have no effect on two Federally listed species present on the Plumas National Forest, *Desmoceras californicus dimorphus* (valley elderberry longhorn beetle) or *Rana aurora draytonii* (California red-legged frog).
- Alternative A may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for *Arabis constancei* (Constance's rock cress). *Cypripedium fasciculatum* (clustered lady's-slipper), or *Lupinus dalesiae* (Quincy lupine).
- The proposed noxious weed treatments under alternatives A and D, which include manual removal, prescribed burning, and herbicide application, are expected to reduce or eliminate infestations of hoary cress, yellow starthistle, Canada thistle, and Scotch broom.
- Under alternative A, 100 percent of the stands treated would meet the desired condition for the reduction of fuels.
- Alternative A would enhance landscape diversity and forest heterogeneity by creating open forest canopy conditions, early seral conditions, and promoting the development of later seral conditions.

Given the purposes and needs, the Responsible Official reviews the proposed action, the other alternatives, and their environmental consequences, in order to determine whether to implement the proposed action as described, select a different alternative, or take no action at this time.

Chapter 1. Purpose of and Need for Action

Document Structure

The Forest Service has prepared this Environmental Impact Statement (EIS) in compliance with the National Environmental Policy Act (NEPA) and other relevant Federal and State laws and regulations. This Environmental Impact Statement discloses the direct, indirect, and cumulative environmental impacts that would result from the proposed action and alternatives. The document is organized into four chapters, and includes appendices and an index:

- **Chapter 1. Purpose and Need for Action:** This chapter briefly describes the proposed action, the need for that action, and other purposes to be achieved by the proposal. This section also details how the Forest Service informed the public of the proposed action and how the public responded.
- **Chapter 2. Alternatives, including the Proposed Action:** This chapter provides a detailed description of the agency's proposed action as well as alternative actions that were developed in response to comments raised by the public during scoping. The end of the chapter includes a summary table comparing the proposed action and alternatives with respect to their environmental impacts.
- **Chapter 3. Affected Environment and Environmental Consequences:** This chapter describes the environmental impacts of the proposed action and alternatives.
- **Chapter 4. Consultation and Coordination:** This chapter provides a list of preparers and agencies consulted during the development of the environmental impact statement.
- **Appendices:** The appendices provide more detailed information to support the analyses presented in the environmental impact statement.
- **Index:** The index provides page numbers by document topic.

Additional documentation, including more detailed analyses of resource specific impacts, may be found in the project record located at the Mt. Hough Ranger District office, 39696 Highway 70, Quincy, CA 95971.

Introduction

This chapter describes the need for resource management activities in the proposed Keddie Ridge Hazardous Fuels Reduction Project area and identifies the project's geographical locations. This chapter also discusses the purposes, objectives, needs, and desired condition buffer widths based on stream types (USDA 1999b, page 2-11) for each proposed activity and the measurement indicators used in the analysis for each objective. The applicable laws, policies, and direction that influence the scope of this analysis are described in this chapter. This chapter also includes information about public involvement, scoping, and the concerns that guided the development of alternatives and the analyses of effects.

Background

Recent high-intensity wildfires fueled by overcrowded stand conditions have caused concern in local communities due to the potential for loss of life and property, timber values, water quality, and wildlife habitat. In the Moonlight and Antelope Complex fires of 2007, over 54,000 acres burned with stand-replacing high severity fire. Approximately 20 California spotted owl protected activity center (PACs) and their associated home range cores areas (HRCAs) were lost due to high severity wildfire effects and were removed from the Plumas National Forest PAC network. The resource values lost were tremendous and much of the existing landscape in the Keddie Ridge Project area resembles the conditions leading up to the fire season of 2007. The Keddie Ridge Project surrounds the communities of Crescent Mills, Greenville, Taylorsville, and all of Indian Valley. The landscape conditions coupled with the proximity of adjacent communities makes the Keddie Ridge Project a priority for treatment.

To address these concerns, the 2004 Sierra Nevada Forest Plan Amendment Record of Decision (SNFPA ROD) allows for full implementation of the Herger-Feinstein Quincy Library Group (HFQLG) Forest Recovery Act Pilot Project. The HFQLG Act established certain vegetation management activities to be implemented in order to test their effectiveness in: reducing the potential size of wildfires, reducing risk to firefighters, and supplying timber for the economic stability of rural communities, while promoting ecological health of a forest through uneven-aged timber management.

Through collaboration with a wide array of stakeholders including the Plumas County Fire Safe Council, Plumas County Board of Supervisors, Plumas County Horseman’s Association, Sierra Access Coalition, Sierra Forest Legacy (SFL), Quincy Library Group (QLG), and local industry groups such as Sierra Pacific Industries, American Forest Resource Council, and California Forestry Association, the Forest Service has identified the following project purposes and needs for action.

Purpose and Need for Action

Purpose 1: Reduce Hazardous Fuel Accumulation

Objective: Modify fire behaviorby reducing hazardous fuels to protect communities, fire fighters, and biological resources.

Need for Action: There is a need for the reduction of hazardous fuelaccumulations within the Keddie Ridge Project area. High densities of small and intermediate-sized trees and heavy fuel loads within forested stands contribute to hazardous accumulations of surface, ladder, and canopy fuels within the project area. These conditions are highly susceptible to crown fire initiation and spread under fire weather conditions, and increase the potential for high-severity stand-replacing fire events. This potential fire behavior leads to increased risk to communities and forest and riparian ecosystems within and adjacent to the Keddie Ridge Project area.

In areas where roads and landings are absent, construction of temporary roads and landings are needed to permit the removal and utilization of material.

Desired Condition: The desired condition is an uneven-aged , multistoried, fire-resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of crown fire. This forest structure has a lower probability of crown fire initiation and spread under 90th percentile weather conditions.

Measures of modifying fire behavior include: predicted flame length s (feet), fire type (surface versus crown fire), and predicted mortality (percent basal area).

Purpose 2: Improve Forest Health

Objective: Modify forest structure, density, and species composition to improve forest health and promote the growth and development of a heterogeneous, uneven-aged, multistoried, fire-resilient forest.

Need for Action: There is a need for the improvement of forest health. The landscape within the project area is dominated by homogeneous, closed canopy mid-seral forests. These forests are characterized by high densities of small and intermediate-sized trees which contribute to stressed stand conditions due to competition for water, light, and nutrients. Growth of trees into larger diameters is limited due to competition and dense forested stands are more susceptible to mortality caused by drought, insects, disease, and fire.

In addition, these high stand densities create closed canopy conditions that are not favorable for regeneration, growth, and development of shade-intolerant and fire resistant species such as ponderosa pine. These shade-intolerant species require more sunlight from open canopy stands and gaps to regenerate successfully.

In areas where roads and landings are absent, construction of temporary roads and landings are needed to permit the removal and utilization of material.

Desired Condition: The desired condition is an uneven-aged, multistoried, fire-resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of crown fire. Stand densities would generally be low, characteristic of an active-fire stand structure, which would promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought, fire, and insect and disease occurrences. In addition, low density, open canopy forest conditions would promote the regeneration, growth, and development of fire-resistant shade intolerant species such as ponderosa pine and black oak, and would contribute to landscape heterogeneity.

Measures of modifying forest structure and species composition include: stand structure attributes (Trees per acre, basal area per acre, relative stand density, species composition (relative abundance of shade-intolerant species), and landscape structure (distribution of CWHR size class and density, average stand diameter, and percent of open canopy forest conditions created).

Purpose 3: Protect and Enhance Habitat for Region 5 Forest Service Sensitive Plant and Wildlife Species

Objective 1: Reduce the threat of high-severity, stand-replacing wildfire within clustered lady's-slipper orchid (*Cypripedium fasciculatum*) and bald eagle nesting habitats.

Objective 2: Modify forest conditions to enhance habitat and support the long-term viability of clustered lady's-slipper and Constance's rock cress (*Arabis constancei*).

Need for Action: Dense stands and high fuel loads increase the risk of high-severity, stand-replacing wildfire in both (a) the primary nesting zone of the Round Valley bald eagle territory and (b) the fourteen clustered lady's-slipper orchid sites located within project treatment units. High-severity wildfires decrease the quality of bald eagle nesting habitat by removing overstory nest structures. In addition, clustered lady's-slipper orchids are intolerant of high-severity fires that eliminate the duff layer or damage the orchid's underground stems. Closed canopy conditions created by high densities of small trees also contribute to a decline in habitat quality for clustered lady's-slipper and Constance's rock cress through decreased light to the forest floor and an increase in leaf litter and duff.

Desired Condition: The desired condition within clustered lady's slipper sites is a fire-resilient forest with sufficient canopy cover that allows for filtered light conditions on the forest floor; a diversity of plants in the understory; adequate soil moisture and duff levels; and the maintenance of soil mycorrhizal (fungal) relationships. The desired condition for Constance's rock cress is a habitat characterized by serpentine soils, open tree canopy, and reduced levels of litter and duff; these conditions promote the expansion of individuals into sites that are currently unsuitable. The desired condition for bald eagles is to provide uneven-age forest structure composed of ponderosa and sugar pine greater than 38 inches diameter at breast height (DBH) with overstory canopy cover of 40-60 percent. Protection and enhancement of nesting habitat by thinning smaller conifers would improve the growth of the residual ponderosa and sugar pines, while surface and ladder fuel reduction would protect the larger tree component for future nest trees.

Measures of reducing threat of high severity wildfire and habitat enhancement include: Region 5 Forest Service sensitive plants (number of occurrences and acres of habitat protected and enhanced) and Region 5 Forest Service sensitive wildlife (stand structure attributes—relative stand density, trees per acre by size class, basal area per acre, canopy cover, average stand diameter and species composition—relative abundance of shade-intolerant species).

Purpose 4: Improve Watershed Health

Objective: Reduce the number of improperly constructed or unmaintained roads.

Need for Action: There is a need for improved watershed health. Roads are the largest single human-caused source of sedimentation and habitat degradation within the project area. Improperly constructed or unmaintained roads may restrict aquatic organism passage and transport sediment to streams and riparian areas, thus degrading water quality and aquatic habitat. The interdisciplinary team (IDT) process for identifying road system needs and roads with resource damage includes a roads analysis consistent with legal requirements (36 CFR 212 Subpart A—Administration of the Forest Transportation System, 16 U.S.C. 551, 23 U.S.C. 205).

Desired Condition: Roads that are needed are maintained and improved to accommodate vehicle traffic. The proposed treatments would provide roads that would ensure safe travel for forest users, and provide a transportation system that is adequate for all resource management needs. Unneeded roads would be eliminated, closed, or obliterated in accordance with the 1988 Forest Plan, as amended, and Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement (FEIS)(August 2010) and Record of Decision (ROD) (September 2010). Roads that are causing a high level of resource damage would be decommissioned or improved. Poorly located roads would be relocated to stable areas. Aquatic species would have access to suitable habitat and would not be restricted from that habitat by roads. Open road densities would be reduced to lessen the impact of roads on wildlife.

Measures of improving watershed health: number of stream crossings, miles of road decommissioned, and miles of road drainage disconnected from streams.

Purpose 5: Reduce Noxious Weed Infestations

Objective: Control the spread and introduction of noxious weeds.

Need for Action: Five invasive plant species of high management concern have been documented within the Keddie Ridge Project area. These include approximately 0.2 acre of hoary cress (*Cardaria draba*), 4 acres of Canada thistle (*Cirsium arvense*), 58 acres of yellow starthistle (*Centaurea solstitialis*), 0.1 acre of Scotch broom (*Cytisus scoparius*), and 45 acres of medusahead (*Taeniatherum caput-medusae*). Past efforts to control these weeds using manual treatment methods have not been effective. Noxious weed species pose a significant threat to ecological function due to their ability to displace native species, alter nutrient and fire cycles, decrease the availability of forage for wildlife, and degrade soil structure. The large existing area occupied by weed species, coupled with the proposed ground-disturbing activities, greatly increase the potential for introduction and spread of noxious weeds.

Desired Condition: The desired condition is to prevent the introduction and establishment of new weeds and to contain and control established infestations so that high priority noxious weed species are reduced or eliminated.

Measures for controlling the spread and introduction of noxious weeds: risk of invasion and spread; effectiveness of the proposed weed treatments; number and acres of noxious weed infestations treated.

Proposed Action

The actions proposed by the Forest Service to meet the purposes and needs are to construct 5,148 acres of Defensible Fuel Profile Zones (DFPZs) through a combination of mechanical thinning, hand thinning, masticating, and prescribed underburning treatments; construct 518 acres of area thinning (AT) outside of DFPZs; construct 287 acres of group selection (GS) within DFPZ and AT units; hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat, 76 acres of Constance's rock cress habitat, and 12 acres within a bald eagle territory; and treat 107 acres of noxious weed infestations using a combination of herbicide applications of aminopyralid or glyphosate, hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. The proposed action is described in more detail in Chapter 2, Alternative A.

Decision Framework

Given the purposes and needs, the Responsible Official reviews the proposed action, the other alternatives, and their environmental consequences, in order to determine whether to implement the proposed action as described, select a different alternative, or take no action at this time.

Forest Plan Direction

Forest Plan

The proposed action and alternatives are guided by the Plumas National Forest Land and Resource Management Plan (PNF LRMP) (USDA 1988) as amended by Herger-Feinstein Quincy Library Group (HFQLG) Final Supplemental Environmental Impact Statement (FSEIS) and Record of Decision (ROD) (USDA 1999a, 1999b, 2003a, 2003b), and the Sierra Nevada Forest Plan Amendment (SNFPA) FSEIS and ROD (USDA 2004a, 2004b). In addition, the HFQLG/SNFPA Implementation Consistency Crosswalk, revised December 2007, provides clarification for applying standards and guidelines for 2004 SNFPA FSEIS and ROD (USDA 2004a, 2004b) and for HFQLG FEIS and ROD (USDA 1999a, 1999b, 2003a 2003b) (HFQLG/SNFPA Implementation Consistency Crosswalk and cover letter, December 12, 2007) (USDA 2007a). This project is being planned under authorization of the Healthy Forest Restoration Act (H.R. 1904; Public Law 108-148; 36 CFR §218 – Predecisional Administrative Review Process).

Land allocations within the Plumas National Forest have been allocated to certain primary uses through three planning processes: the original PNF LRMP (USDA 1988) development process, the HFQLG FEIS, FSEIS, and RODs (USDA 1999a, 1999b, 2003a, 2003b), and the SNFPA ROD (USDA 2004a, 2004b). Each of these plan components includes standards and guidelines for land and resource management unique to each land allocation. Many of these allocations overlap. During the life of the HFQLG Act Pilot Project, HFQLG land allocations are to be employed for vegetation management projects, with one exception (SNFPA ROD allocation for Northern goshawk PACs).

Certain allocations (called prescriptions) in the PNF LRMP are still applicable in whole or in part, because they were not superseded by three amendments. Those allocations still in effect for the Keddie Ridge Project area are included in appendix J of this EIS and discussed further below.

The PNF LRMP (USDA 1988) displays management areas, which include descriptions, standards and guidelines, prescription allocations, and management objectives specific to each management area (page 4-113). Management areas that overlap with the Keddie Ridge Project area include: Rich (#20), Grizzly Ridge (#23), Butt Lake (#26), Indian Valley (#27), Lights Creek (#28), Antelope (#29), and Ward (#30). Management areas that overlap with proposed treatment units within the Keddie Ridge Project area include: Indian Valley (#27) and Lights Creek (#28). Because Rich, Grizzly Ridge, Butt Lake, Antelope, and Ward do not overlap with treatment units and very small portions of the management areas overlap with the Keddie Ridge Project area, these management areas are removed from further discussion. Of the management areas that overlap with proposed treatment units, prescription allocations that apply include: Rx5-Recreation Area Prescription; Rx3-Special Interest Areas Prescription; Rx6-Developed Recreation Site Prescription; Rx7-Minimal Management Prescription; Rx8-Semi-Primitive Area Prescription; Rx10-

Visual Retention Prescription; Rx13-Goshawk Habitat Prescription; Rx14-Visual Partial Retention Prescription; Rx 15-Timber Emphasis Prescription; and Rx16-Intensive Ranger. Areas of general direction and standards and guidelines are located on pages 4-274 – 4-293 and in appendix J of this EIS.

Herger-Feinstein Quincy Library Group Forest Recovery Act

On October 21, 1998, the President of the United States signed the Department of the Interior and Related Agencies Appropriations Act, including section 401—the Herger-Feinstein Quincy Library Group Forest Recovery Act (HFQLG Act). The HFQLG Act states that the Secretary of Agriculture, acting through the Forest Service, and after completion of an EIS, shall conduct a pilot project for five years on federal lands in the Lassen and Plumas National Forests and the Sierraville District of the Tahoe National Forest.

The HFQLG Pilot Project is designed to test and demonstrate the effectiveness of certain fuels and vegetation management activities in meeting ecologic, economic, and fuel-reduction objectives. Full implementation of the HFQLG Pilot Project would result in an annual average of 8,700 acres of group selection across the Pilot Project Area, consistent with protection of ecosystems, watersheds, and other forest resources; good silvicultural practices; and economic efficiency.

Herger-Feinstein Quincy Library Group Forest Recovery Act EIS, Supplemental EIS, Records of Decision (1999 and 2003) and Appropriations Acts

The HFQLG Act EIS was completed on August 17, 1999, and the Record of Decision was signed on August 20, 1999 (USDA 1999b). The Record of Decision amended the land and resource management plans for the three National Forests (Plumas, Lassen, and Tahoe) and gave direction to implement the resource management activities required by the HFQLG Act. The Record of Decision on the HFQLG Final Supplemental EIS addressing DFPZ maintenance was adopted on July 31, 2003 (USDA 2003b). In February 2003, the Department of the Interior and Related Agencies Appropriations Act was signed and extended the HFQLG Pilot Project legislation by another five years. The 2008 Consolidated Appropriations Act extended the HFQLG Pilot project to September 30, 2012. It also applied some portions of the Healthy Forest Restoration Act (Sections 104-106) to HFQLG projects. These sections relate to environmental analysis, public notice, comment and objection processes, and judicial review. In March 2009, the Omnibus Appropriations Act amended this, clarifying that Section 106 of the Healthy Forest Restoration Act (related to expedited judicial review) shall apply to all HFQLG projects, while Sections 104 and 105 (related to environmental analysis and objection processes) may be applied to HFQLG projects.

The 1999 HFQLG Record of Decision (pages 8-10) displays the changes in management direction applicable to the HFQLG Pilot Project Area. Amendments to the PNF LRMP are discussed in detail in the HFQLG Final Environmental Impact Statement on pages 2-6 – 2-18. Land allocations that apply to the Pilot Project area include offbase and deferred lands, late-successional old-growth stands (ranks 4 and 5), California spotted owl protected activity centers (PAC), spotted owl habitat areas (SOHA), riparian habitat conservation areas (RHCAs), and the National Forest System (NFS) lands outside these allocations that are available for vegetation and fuels management activities.

NFS lands outside of the above mentioned allocations and available for vegetation and fuels management activities specified in the HFQLG Act have specific standards and guidelines listed on pages 8-10 of the HFQLG ROD, pages 2-6 – 2-18 of the HFQLG FEIS, and appendix J of this EIS.

Sierra Nevada Forest Plan Amendment Final Supplemental EIS (2004)

In January 2004, the Regional Forester signed the SNFPA Final Supplemental EIS Record of Decision, which replaced the 2001 Record of Decision on the SNFPA final EIS and changed management direction to allow full implementation of the HFQLG Pilot Project, consistent with the goals identified in the HFQLG Act. The 2001 SNFPA final EIS and Record of Decision are incorporated by reference in the 2004 Record of Decision on the SNFPA Final Supplemental EIS.

The 2004 Record of Decision on the SNFPA Final Supplemental EIS directed the Plumas National Forest to implement the HFQLG Pilot Project, which includes creation of DFPZs for the proposed project. These treatments are needed in order to limit the potential size and loss of resources from large high-intensity wildfires. DFPZs are strategically located and designed strips of land where surface fuels (excess down woody material), ladder fuels, and canopy fuels are treated so that large, destructive canopy fires would lose intensity and transition to surface fires. DFPZs are wide enough to capture short-range spot fires in the treated area and are designed to provide fire suppression personnel a safe location from which to take fire-suppression actions. DFPZs are usually located along roads, ridgetops, meadows, or rocky areas to enhance their effectiveness and accessibility.

The 2004 SNFPA Record of Decision (pages 68 and 69) displays the standards and guidelines applicable to the HFQLG Pilot Project Area. Land allocations that apply to this proposal, in addition to the PNF LRMP and HFQLG ROD and FEIS, include California spotted owl home range core areas (HRCAs), Northern goshawk PACs, wildland urban interface (WUI), and extended WUI.

NFS lands outside of the above mentioned allocations and available for vegetation and fuels management activities specified in the HFQLG Act have specific standards and guidelines listed on pages 68 and 69 of the SNFPA ROD (Table 2) and appendix J of this EIS.

Public Involvement

The Keddie Ridge Project has been listed in the Plumas National Forest quarterly Schedule of Proposed Actions (SOPA) since December 6, 2006. A Notice of Intent (NOI) to prepare an Environmental Impact Statement for the Keddie Ridge Project was published in the Federal Register on Thursday, April 1, 2010. The notice asked that comments on the proposed action be received by Friday, April 16, 2010. The purpose of the scoping process was to inform the public about the proposed action and purpose and need in order to seek different points of view on the pending action and issues to be addressed during the project analysis period. In addition, as part of the public involvement process and collaboration requirements under the Healthy Forest Restoration Act (HFRA), the Forest Service held two open houses – September 15, 2009 at Mt. Hough Ranger District in Quincy, California and June 16, 2010, at Greenville Town Hall in Greenville, California. Announcements for each open house were published in the *Feather River Bulletin* and informational flyers were sent to the Plumas National Forest key contacts, including media. The Forest Service also held individual collaboration meetings with interest groups from July throughout April 2010 and hosted a field trip for all interested parties on May 26, 2010.

One verbal and thirteen written comments on the proposed action were received during the scoping period. The scoping comments and issues presented in the comments are summarized in appendix G of this EIS. A compilation of scoping comments is located in the project record at Mt. Hough Ranger District in Quincy, CA.

The following individuals, organizations, and agencies provided scoping comments on the proposed action and/or comments during the official 30 day scoping period:

- Darca Morgan, Craig Thomas, and Pat Gallagher, Sierra Forest Legacy
- Michael DeSpain, Mechoopda Indian Tribe of Chico Rancheria
- Tom Downing, Sierra Pacific Industries
- Melany Johnson, Susanville Indian Rancheria
- Ren Reynolds, Estom Yumeka Tribe of Enterprise Rancheria
- Stephanie Skophammer, U.S. Environmental Protection Agency
- Frank Stewart, Counties' Quincy Library Group Forester
- Hank Alrich
- Vanessa Vasquez, Californians for Alternatives to Toxics
- Dixie Dursteler-Harrington
- Chad Hanson, John Muir Project
- Steven Brink, California Forestry Association
- Rex Fisher
- Jerry Hurley, Plumas County Fire Safe Council

The Forest Service initiated an official 45 day comment period once the Notice of Availability was published in the Federal Register on February 4, 2011. A comment period notice was also published in the *Feather River Bulletin* on the following Wednesday, February 9, 2011. Ten comments were received from three agencies and seven organizations. A response to comments can be found in appendix G of this EIS. A compilation of comments received during the comment period is located in the project record at Mt. Hough Ranger District in Quincy, CA.

The following individuals, organizations, and agencies provided comments during the official 45 day comment period:

- Tom Downing, Sierra Pacific Industries
- Kathleen Goforth, U.S. Environmental Protection Agency
- Bill Wickman, American Forest Resource Council
- Karina Silvas-Bellanca, Craig Thomas, Pat Gallagher, and Darca Morgan, Sierra Forest Legacy
- Chad Hanson, John Muir Project
- Bill Wickman, Plumas County Economic Recovery Committee
- John Sheehan, Plumas Corporation
- Frank Stewart, Counties' Quincy Library Group Forester
- Patricia Sanderson Port, United States Department of the Interior

The final EIS (FEIS) will be sent to agencies, organizations, and individuals that submitted comments throughout the project planning process, individuals who requested a copy, and thirteen reviewing agencies (listed in chapter 4 of this EIS).

Issues

Comments from the public, other agencies, and tribes were used to formulate issues concerning the proposed action. Issues are phrased as cause-effect relationships, the concept of describing a specific action and the environmental effect(s) expected to result from that action applies whether one is using an EA or an EIS. Issues (cause-effect relationships) serve to highlight effects or unintended consequences that may occur from the proposed action, providing opportunities during the analysis to explore alternative ways to meet the purpose and need for the proposal while reducing adverse effects. The Mt. Hough Interdisciplinary Team (IDT) separated the issues into two groups: significant and non-significant. Significant issues were defined as those where there may be a cause-effect relationship between a proposed action and a significant effect and the disclosure of that effect is documented in an EIS. Non-issues were identified as those: 1) outside the scope of the proposed action; 2) already decided by law, regulation, Forest Plan, or other higher level decision; 3) irrelevant to the decision to be made; 4) conjectural and not supported by scientific or factual evidence; or 5) the comment could not be phrased as a cause-effect relationship. Non-significant issues were identified as those not resulting in a significant effect. The Council on Environmental Quality (CEQ) NEPA regulations explain this delineation in Sec. 1501.7, "…identify and eliminate from detailed study the issues which are not significant or which have been covered by prior environmental review (Sec. 1506.3)…". A list of non-significant issues and reasons why they were found non-significant may be found in the project record located at the Mt. Hough Ranger District in Quincy, CA.

As for significant issues, the Forest Service did not identify any significant issues during scoping. This is because the cause and effect relationship identified, although logical, is not expected to have a significant effect. A list of issues and non-significance determinations from comments is available in appendix G of this EIS. Two alternatives, D and E, were requested by commenters who submitted scoping comments during the scoping period.

Chapter 2. Alternatives, Including the Proposed Action

Introduction

This chapter describes and compares the alternatives considered for the Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project). It describes both alternatives considered in detail and those eliminated from detailed study. The end of this chapter presents the alternatives in tabular format so that the alternatives and their environmental impacts can be readily compared.

Alternatives Considered in Detail

Based on requests identified through public comment on the proposed action, the Forest Service developed two alternative proposals that achieve the purpose and need differently than the proposed action. In addition, the Forest Service is required to analyze a no action alternative and a non-commercial funding alternative. The proposed action, other action alternatives, and the no action alternative are described in detail below.

Alternative A

The Proposed Action – Collaboration Alternative (Preferred Alternative)

Collaboration is required under the Healthy Forest Restoration Act. Collaboration should occur when developing the proposed action. In collaboration, stakeholders work together to: 1) identify and better understand each other's interests, and 2) refine project design so as to better meet all interests within the Responsible Official's decision space and criteria. Ideas and suggestions received during the scoping period were applied to this alternative where appropriate and applicable.

Individuals and organizations that expressed interest during previous scoping efforts (December 2006) were contacted to schedule collaboration meetings. Twelve individuals and organizations expressed interest in the Keddie Ridge Project. Meetings were held from July 31 through September 1, 2009 and included the following organizations: Plumas County Fire Safe Council, Plumas County Board of Supervisors, Plumas County Horseman's Association, Sierra Access Coalition, and Sierra Forest Legacy. Collaboration efforts continued with the Quincy Library Group (QLG), Sierra Forest Legacy, and local industry groups such as Sierra Pacific Industries, American Forest Resource Council, and California Forestry Association through April 2010.

Many variables were considered in developing the proposed action and associated treatment unit specific prescriptions, such as purpose and need, proposed treatment, California Wildlife Habitat Relationship (CWHR) system type, size, and density, land allocation, visual quality objectives, and guidance from the General Technical Report PSW–GTR-220, *An Ecosystem management Strategy for Sierran Mixed-Conifer Forests* (USDA 2009).

Unit specific prescriptions and maps are located in appendix B, and address Riparian Habitat Conservation Areas (RHCAs), and California Wildlife Habitat Relationship (CWHR) system specific canopy cover (CC), general retention size for trees, and post-treatment underburning.

Each prescription is unique and the variables that change are: canopy cover (CC), general retention size for trees, and the land allocation for which these variables apply. Overall, the proposed action applies more restrictive prescriptions to RHCAs, CWHR 5M/5D, and California spotted owl home range core area (HRCA) land allocations, as they relate to CCs and general retention size for trees.

Under alternative A, Defensible Fuel Profile Zones, Area Thinning, Group Selection, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, and noxious weed treatments, would be implemented to accomplish the purpose and need. All live trees greater than or equal to 30 inches diameter at breast height (DBH) would be retained throughout all treatments and prescriptions, except to allow for operations. Impacts to live trees greater than or equal to 30 inches DBH would be minimized as much as practicable.

Defensible Fuel Profile Zones (DFPZs)

DFPZs would be constructed using a combination of hand thinning, piling, and burning; masticating; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within DFPZ units would be treated. Within specific units, borax, a fungicide would be applied to pine stumps greater than 14 inches within one day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease. Approximately 5,175 acres of DFPZs would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (1,026 acres). Hand thin, pile, and burn within approximately 76 acres of Constance’s rock cress habitat and five acres of clustered lady’s slipper habitat.
- Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH (357 acres).
- Mechanically thin trees less than 30 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-30 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
    - Thin to 30-40 percent canopy cover (CC), retain all live trees greater than or equal to 30 inches DBH; **except** in **CWHR 5M/5D**, thin to 40-50 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in **RHCAs** thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (824 acres).
    - Thin to 30-40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; **except** in **CWHR 4M/4D**, thin to 40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in **CWHR 5M/5D** thin to 40-50 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in **RHCAs**, thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (255 acres).

  - Thin to 30-40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; **except** in **CWHR 5M/5D** thin to 40-50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; in **RHCAs** thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (870 acres).
  - Thin to 40-50 percent CC, generally retain live trees greater than or equal to 20 inches DBH, and underburn (180 acres).
  - Thin to 30-50 percent CC, generally retain live trees greater than or equal to 12 inches DBH, and underburn (206 acres).
  - In units 45, 46, 49, and 50, apply borax to pine stumps greater than 14 inches diameter within one day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease.
- Low to moderate intensity prescribed underburn (1,456 acres). Two underburn units, 38 and 39, overlap with a SOHA. The total amount of SOHA acres proposed for underburning is 106 acres and would be underburned at low intensity.

Area Thinning (AT)

Area thinning units would be constructed using a combination of hand thinning, piling, and burning; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within AT units would be treated. Approximately 494 acres of AT would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (231 acres). Approximately four acres of treatment would occur within clustered lady's slipper habitat.
- Mechanically thin trees less than 30 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-24 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
  - Thin to 30-40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; **except** in **CWHR 4M/4D**, thin to 40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in **CWHR 5M/5D** thin to 40-50 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in **RHCAs**, thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (262 acres). Approximately 46 acres of mechanical thinning would occur within the primary nesting zone of the Round Valley bald eagle territory.

Group Selections (GSs)

Group selection is proposed in mechanical thinning units within DFPZs and AT units (284 acres) using mechanical equipment. Group selection involves harvest of trees less than 30 inches in diameter in small (0.5 to 2 acres) patches. All live trees greater than or equal to 30 inches DBH would be retained. Healthy, vigorous, undamaged, shade intolerant trees 20 inches in diameter and greater would be considered for retention for seed tree and forest structure purposes, where appropriate. Within units 45, 46, 49, and 50, borax, a fungicide would be applied to pine stumps greater than 14 inches within one day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease.

Watershed Improvements

Approximately 0.6 mile of NFS road 28N38A would be proposed for decommissioning upon project completion. Approximately 0.4 mile of non-system road, a continuation of NFS road 28N38A, would be proposed for decommissioning upon project completion.

Roads that are to remain open but are improperly constructed or unmaintained would be improved. Treatments range from light brushing with no drainage improvements to heavy brushing and large drainage improvements. Drainage improvements may include: out sloping road segments, installing armored rolling dips, or replacing culverts. Improvements to the road drainage system and road surface prism would be considered for 100 miles of road within the watershed analysis area. Rolling dips, which would likely be one of the most commonly prescribed road improvements for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road. This estimate may vary depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips to sufficiently disconnect the road drainage system from nearby stream channels would be determined by District watershed staff. Refer to appendix C for a list of these roads.

Noxious Weeds

Five noxious weed species would be treated using a combination of herbicide applications, manual removal, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. The number of acres proposed for each treatment (or combination of treatments) is provided in Table 1. It is important to note that the noxious weed treatment acres presented in this document represent the maximum area proposed for treatment and take into account the projected amount of spread that may occur prior to project implementation (i.e. over a period of two to three years). Species specific noxious weed treatments proposed under alternative A are included in Table 2.

Table 1. Noxious Weed Treatments and Acres Proposed under Alternatives A and D

Treatment	Acres
Rx 1: aminopyralid	16
Rx 1: aminopyralid / Rx 3: spring underburn	45
Rx 2: glyphosate	0.8
Rx 2: glyphosate / Rx 3: spring underburn	0.2
Rx 3: spring underburn	45
Rx 4: hand pull	0.2
Total	107

Table 2. Proposed Treatments for Noxious Weeds under Alternatives A and D

Noxious Weed Species	Proposed Treatments
Centaurea solstitialis **(yellow starthistle)**	Approximately 58 acres would be treated with the herbicide aminopyralid. Spring underburning and/or revegetation using native seed would be considered within treatment units at a site-specific level. Follow-up treatments would include a combination of hand pulling, cutting with a hand-held string trimmer (i.e. weed whacker), or flaming with a propane torch. Revegetation of treated sites using native seed would be considered at a site-specific level.
Taeniatherum caput-medusae **(medusahead)**	Spring underburning would be used as a treatment on approximately 45 acres. Infestations that are considered to be a high risk for spread (i.e. on roads and landings) may be treated by flaming with a propane torch. Revegetation of treated sites using native seed would be considered at a site-specific level.
Cirsium arvense **(Canada thistle)**	Treatment would include the application of two herbicides: approximately 3.5 acres of aminopyralid (in upland areas) and 0.8 acre of glyphosate (in lowland areas). Underburning and/or revegetation of treated sites using native seed would be considered at a site-specific level.
Cardaria draba **(hoary cress)**	Approximately 0.2 acres would be treated with the herbicide glyphosate. Manual methods, such as hand pulling and digging, would be used as a follow-up treatment. Revegetation of treated sites using native seed would be considered at a site-specific level.
Cytisus scoparius **(Scotch broom)**	Treatment of approximately 0.1 acres would consist of manual methods, primarily hand pulling and removal using a weed wrench.

Alternative B

No Action Alternative

Under the no action alternative, the proposed action would not take place. No DFPZs, AT, GS, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, or noxious weed treatments would be implemented to accomplish the purpose and need.

Alternative C

Non-Commercial Funding Alternative

A recent court ruling requires that all projects with a singular purpose and need for fuels reduction, or with multiple purposes and needs that include fuels reduction, must have a non-commercial funding alternative. A non-commercial funding alternative is an alternative where the sole purpose is to achieve the fuels reduction element of the purpose and need and where all the proposed treatments are solely directed at reducing hazardous fuels. In a non-commercial funding alternative, there can be no additional timber harvesting added beyond that needed to meet the fuel reduction purpose and need (*Sierra Forest Legacy v. Mark Rey*, Case 2:05-cv-00205-MCE-GGH, Morrison C. England, Jr., United States District Court Judge, United States District Court, Eastern District of California, November 4, 2009).

Alternative C includes DFPZ and AT treatments, which would be implemented to accomplish the purpose and need for modifying fire behavior only. No other treatments proposed under any other action alternative would be proposed under this alternative. All live trees greater than or equal to 12 inches DBH would be retained throughout all treatments and prescriptions, except to allow for operations. Impacts to live trees greater than or equal to 12 inches DBH would be minimized as much as practicable.

Defensible Fuel Profile Zones (DFPZs)

DFPZs would be constructed using a combination of hand thinning, piling, and burning; masticating; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within DFPZ units would be treated. Approximately 5,431 acres of DFPZs would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (1,026 acres). Hand thin, pile, and burn within approximately 76 acres of Constance’s rock cress habitat and five acres of clustered lady’s slipper habitat.
- Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH (357 acres).
- Mechanically thin trees less than 12 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-12 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
    - Thin to 30-40 percent canopy cover (CC), retain all live trees greater than or equal to 12 inches DBH; **except** in **CWHR 5M/5D**, thin to 40-50 percent CC, generally retain all live trees greater than or equal to 12 inches DBH; in **RHCAs** thin to 50 percent CC, generally retain live trees greater than or equal to 12 inches DBH; and underburn (2,591 acres). Spring underburn in areas infested with noxious weeds (3.6 acres).
- Low to moderate intensity prescribed underburn (1,456 acres). Two underburn units, 38 and 39, overlap with a SOHA. The total amount of SOHA acres proposed for underburning is 106 acres and would be underburned at low intensity. Approximately 80 acres, which are infested with noxious weeds, would be burned in the spring to reduce the risk of spread.

Area Thinning (AT)

Area thinning units would be constructed using a combination of hand thinning, piling, and burning; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within AT units would be treated. Approximately 522 acres of AT would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (231 acres). Approximately four acres of treatment would occur within clustered lady's slipper habitat. Underburning would occur in the spring within areas of noxious weed infestations (4.6 acres).
- Mechanically thin trees less than 12 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-12 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
    - Thin to 30-40 percent CC, retain all live trees greater than or equal to 12 inches DBH; **except** in **CWHR 4M/4D**, thin to 40 percent CC, retain all live trees greater than or equal to 12 inches DBH; in **CWHR 5M/5D** thin to 40-50 percent CC, retain all live trees greater than or equal to 12 inches DBH; in **RHCAs**, thin to 50 percent CC, retain all live trees greater than or equal to 12 inches DBH; and underburn (290 acres). Approximately 46 acres of mechanical thinning would occur within the primary nesting zone of the Round Valley bald eagle territory.

Alternative D

2001 Sierra Nevada Forest Plan Amendment (SNFPA) Record of Decision (ROD) Consistent Alternative

This alternative was developed under the 2001 SNFPA ROD (USDA 2001a, 2001b) in response to scoping comments. Under the 2001 SNFPA ROD consistent alternative, DFPZs, AT, GS, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, and noxious weed treatments would be implemented to accomplish the purpose and need. There are fewer acres proposed under this alternative because the 2001 SNFPA ROD incorporates different prescriptions and applies retention levels for specific land allocations compared to the 2004 SNFPA ROD (alternatives A and E). All live trees greater than or equal to 20 inches DBH would be retained throughout all treatments and prescriptions, except to allow for operations. Impacts to live trees greater than or equal to 20 inches DBH would be minimized as much as practicable.

Defensible Fuel Profile Zones (DFPZs)

DFPZs would be constructed using a combination of hand thinning, piling, and burning; masticating; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within DFPZ units would be treated. Within specific units, borax, a fungicide would be applied to pine stumps greater than 14 inches within one day of cutting, to prevent the introduction and spread of

Heterobasidion root disease. Approximately 4,976 acres of DFPZs would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (1,464 acres). Hand thin, pile, and burn within approximately 76 acres of Constance's rock cress habitat and five acres of clustered lady's slipper habitat.
- Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing. Retain all hardwoods greater than 3 inches DBH (357 acres).
- Mechanically thin trees less than 20 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-20 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
    - Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH, and leave 25 percent of the stand untreated; and underburn (71 acres).
    - Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH, and leave 15 percent of the stand untreated; and underburn (709 acres).
    - Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH; **except** in **CWHR 5M/5D** thin to 50 percent CC retain all live trees greater than or equal to 12 inches DBH, and leave 25 percent of the stand untreated; and underburn (574 acres).
    - Thin to minimum 50 percent CC while only reducing the CC less than 10 percent, retain all live trees greater than or equal to 12 inches DBH, and leave 25 percent of the stand untreated; and underburn (346 acres).
    - In units 45, 46, 49, and 50, apply borax to pine stumps greater than 14 inches within one day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease.
- Low to moderate intensity prescribed underburn (1,456 acres). Two underburn units, 38 and 39, overlap with a SOHA. The total amount of SOHA acres proposed for underburning is 106 acres and would be underburned at low intensity.

Area Thinning (AT)

Area thinning units would be constructed using a combination of hand thinning, piling, and burning; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within AT units would be treated. Approximately 467 acres of AT would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (301 acres). Approximately four acres of treatment would occur within clustered lady's slipper habitat.
- Mechanically thin trees less than 20 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-20 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:

- Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH, and leave 25 percent of the stand untreated; and underburn (26 acres). This would occur within the primary nesting zone of the Round Valley bald eagle territory.
- Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH; **except** in **CWHR 5M/5D**, thin to 50 percent CC, retain all live trees greater than or equal to 12 inches DBH, and leave 25 percent of the stand untreated; and underburn (140 acres).

Group Selection (GS)

No group selection would occur under this alternative.

Watershed Improvements

Approximately 0.6 mile of NFS road 28N38A would be proposed for decommissioning upon project completion. Approximately 0.4 mile of non-system road, a continuation of NFS road 28N38A, is proposed for decommissioning upon project completion.

Roads that are to remain open but are improperly constructed or unmaintained would be improved. Treatments range from light brushing with no drainage improvements to heavy brushing and large drainage improvements. Drainage improvements may include: outsloping road segments, installing armored rolling dips, or replacing culverts. Improvements to the road drainage system and road surface prism would be considered for 100 miles of road within the watershed analysis area. Rolling dips, which would likely be one of the most commonly prescribed road improvements for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road. This estimate may vary depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips to sufficiently disconnect the road drainage system from nearby stream channels would be determined by District watershed staff. Refer to appendix C for a list of these roads.

Noxious Weeds

Five noxious weed species would be treated using a combination of herbicide applications, manual removal, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. The noxious weed prescriptions proposed under alternative D are identical to those listed under the proposed action and can be found in Table 1 and Table 2.

Alternative E

2004 Sierra Nevada Forest Plan Amendment (SNFPA) Record of Decision (ROD) Consistent Alternative

This alternative was developed under the 2004 SNFPA ROD in response to scoping comments. Under alternative E, DFPZs, AT, GS, R5 Forest Service sensitive wildlife and plant species treatments, watershed treatments, and limited noxious weed treatments would be implemented to accomplish the purpose and need. This alternative follows the direction and standards and guidelines for the HFQLG Pilot Project Area and 2004 SNFPA ROD land allocations (USDA 2004b, Table 2, pages 68 and 69). All live trees greater than or equal to 30 inches DBH would be retained throughout all treatments and prescriptions, except to allow for operations. Impacts to live trees greater than or equal to 30 inches DBH would be minimized as much as practicable.

Defensible Fuel Profile Zones (DFPZs)

DFPZs would be constructed using a combination of hand thinning, piling, and burning; masticating; mechanical thinning; and prescribed underburning treatments. Riparian Habitat Conservation Areas (RHCAs) within DFPZ units would be treated. Approximately 5,134 acres of DFPZs would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (1,026 acres). Hand thin, pile, and burn within approximately 76 acres of Constance's rock cress habitat and five acres of clustered lady's slipper habitat.
- Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH (357 acres).
- Mechanically thin trees less than 30 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-30 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:
    - Thin to 30-40 percent CC, retain all live trees greater than or equal to 30 inches DBH; **except** in **CWHR 5M/5D**, thin to 40 percent CC, retain all live trees greater than or equal to 30 inches DBH; in **RHCAs**, thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (2,242 acres).
    - Thin to 40-50 percent CC, retain all live trees greater than or equal to 30 inches DBH; **except** in **RHCAs** thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (53 acres).
- Low to moderate intensity prescribed underburn (1,456 acres). Two underburn units, 38 and 39, overlap with a SOHA. The total amount of SOHA acres proposed for underburning is 106 acres and would be underburned at low intensity.

Area Thinning (AT)

Area thinning units would be constructed using a combination of hand thinning, piling, and burning; mechanical thinning; and prescribed underburn treatments. Riparian Habitat Conservation Areas (RHCAs) within AT units would be treated. Approximately 493 acres of AT would be constructed through the following treatments and associated prescriptions:

- Hand thin, pile, and burn trees less than 8 inches DBH and underburn (231 acres). Approximately four acres of treatment would occur within clustered lady's slipper habitat.
- Mechanically thin trees less than 30 inches DBH utilizing ground-based and skyline logging systems. Trees less than 10 inches DBH would be removed as biomass and trees between 10-30 inches DBH would be removed as sawlogs. In some skyline units (as described under design criteria common to all action alternatives), trees less than 10 inches DBH would be hand thinned, piled, and burned. The following prescriptions would be implemented:

- Thin to 40-50 percent CC, retain all live trees greater than or equal to 30 inches DBH; **except** in **RHCAs** thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn (261 acres). Approximately 46 acres of mechanical thinning would occur within the primary nesting zone of the Round Valley bald eagle territory.

Group Selection (GS)

Group selection is proposed in mechanical thinning units within DFPZs and AT units (326 acres) using mechanical equipment. Group selection involves harvest of trees less than 30 inches in diameter in small (0.5 to 2 acres) patches. All live trees greater than or equal to 30 inches DBH would be retained.

Watershed Improvements

Approximately 0.6 mile of NFS road 28N38A would be proposed for decommissioning upon project completion. Approximately 0.4 mile of non-system road, a continuation of NFS road 28N38A, would be proposed for decommissioning upon project completion.

Roads that are to remain open but are improperly constructed or unmaintained would be improved. Treatments range from light brushing with no drainage improvements to heavy brushing and large drainage improvements. Drainage improvements may include: outsloping road segments, installing armored rolling dips, or replacing culverts. Improvements to the road drainage system and road surface prism would be considered for 100 miles of road within the watershed analysis area. Rolling dips, which would likely be one of the most commonly prescribed road improvements for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road. This estimate may vary depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips would be determined by district watershed staff in order to sufficiently disconnect the road drainage system from nearby stream channels. Refer to appendix C for a list of these roads.

Noxious Weeds

Three noxious weed species would be treated using a combination of manual removal, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. No herbicides are proposed in alternative E. The number of infested acres proposed for each treatment (or combination of treatments) is provided in Table 3. It is important to note that all of the noxious weed treatment acres presented in this document represent the maximum area proposed for treatment and take into account the projected amount of spread that may occur prior to project implementation (i.e. over a period of two to three years). An overview of the noxious weed treatments proposed under alternative E is included in Table 4.

Table 3. Noxious Weed Treatments and Acres Proposed under Alternative E

Treatment	Acres
Rx 3: spring underburn	88.6
Rx 4: hand pull	0.4
Total	89

Table 4. Treatments for Noxious Weeds under Alternative E

Noxious Weed Species	Proposed Treatments
***Centaurea solstitialis* (yellow starthistle)**	Approximately 44 acres would be treated with spring underburning. Approximately 0.3 acres would be treated with hand-pulling alone. Revegetation using native seed would be considered within treatment units at a site-specific level. Follow-up treatments would include a combination of hand pulling, cutting with a hand-held string trimmer (i.e. weed whacker), or flaming with a propane torch.
***Taeniatherum caput-medusae* (medusahead)**	Spring underburning would be used as a treatment on approximately 45 acres. Infestations that are considered to be a high risk for spread (i.e. on roads and landings) may be treated by flaming with a propane torch. Revegetation using native seed would be considered within treatment units at a site-specific level.
***Cirsium arvense* (Canada thistle)**	No treatments are proposed under this alternative due to feasibility and effectiveness constraints.
***Cardaria draba* (hoary cress)**	No treatments are proposed under this alternative due to feasibility and effectiveness constraints.
***Cytisus scoparius* (Scotch broom)**	Treatment of approximately 0.1 acres would consist of manual methods, primarily hand pulling and removal using a weed wrench.

Design Criteria Common to All Action Alternatives

This section presents a series of tables (Table 5 through Table 13) that contain the design criteria for the treatments proposed in the action alternatives. The design criteria are part of the project design, apply to the proposed treatments, and were developed to reduce or avoid adverse environmental effects of the proposed treatments.

Table 5. Design Criteria for DFPZs and Area Thinning

Criterion	Actions
Ground-based Harvesting and Yarding	Mechanical harvesting and whole-tree yarding would be used to remove commercial sawlog and biomass trees. Trees greater than or equal to 10 inches DBH would be removed as sawlog product and trees less than 10 inches DBH would be removed as biomass product. Tops and limbs would be yarded to the landing and removed as a product. Ground-based equipment would be restricted to slopes less than 35 percent. Exceptions may be made for short pitches (less than 100’) within the interior of units where slopes exceed these limits. When units have inaccessibly steep

Criterion	Actions
	inclusions of steeper ground, sawlog and biomass products may be end-lined.
Skyline Harvesting and Yarding	In units 46, 50, 54, 55, 95, and 99a: Skyline yarding would be used to remove commercial sawlogs. Trees greater than or equal to 10 inches DBH would be removed as sawlog product. Harvested trees would be limbed, topped, and this activity slash would be hand piled. Trees less than 10 inches DBH would be hand thinned, piled, and burned post-treatment. In units 2, 4, 5, 21, 27, 28, 29 56, and 59: Whole-tree yarding would be used to remove commercial sawlog and biomass trees. Trees greater than or equal to 10 inches DBH would be removed as a sawlog product. Trees less than 10 inches DBH would be removed as a biomass product. Tops and limbs would be yarded to the landing and removed as a product. Skyline yarding would require one end suspension with full suspension over intermittent and perennial streams. The corridor would not be wider than 20 feet. The width for lateral yarding to the skyline corridor would be 75 feet on either side of the mainline. Lateral yarding would not require lift. When there are short inclusions of side hill within the corridor, allow side hill yarding. The top 100 feet of the skyline corridor would be rehabilitated with weed-free straw mulch and native seed.
Residual species preference	Retain the largest, most vigorous dominant and codominant trees to create a residual stand that would be comprised of larger fire-resilient trees. Species preference would be determined by forest type. In general, prefer to retain shade-intolerant species including rust-resistant sugar pine, black oak, ponderosa and Jefferey pine, and Douglas-fir.
Residual surface fuels	Maintain adequate cover of surface fuels, litter, duff, and large woody debris to maintain habitat values, reduce potential erosion, and meet soil standards for woody debris and ground cover. Retain surface fuels (less than 12 inches diameter) at a level that would result in projected flame lengths of less than 4 feet under 90th percentile weather conditions. This generally corresponds to approximately 5 tons or less of surface fuels per acre, or a fuel model 8 or 9, depending on the forest type. Fuel model 8 and 9 are representative of the desired condition for surface fuels for fir dominated and pine dominated stands, respectively. Retain large woody debris (greater than 12 inches diameter), where they exist, at 10 to 15 tons per acre of the largest down logs. Where needed, jackpot burn, or machine pile and burn extensive areas of deadfall, where feasible, in terms of equipment operability and reduced chance of excessive scorch-related mortality upon burning of these piles. Based on post treatment evaluations, underburn, jackpot burn, machine pile and burn, and/or hand pile and burn to treat natural and activity-generated fuels.
Snag retention	Retain the number of snags per acre appropriate for each forest type unless removal is required to allow for operability. In Sierra mixed conifer types and ponderosa pine forest types, retain four of the largest snags per acre. In the red fir forest type, retain six of the largest snags per acre. Snags larger than 15 inches DBH and 20 feet in height would be used to meet this guideline.
TES treatment areas and control areas	Bald Eagle: Within 12 acres immediately surrounding the nest tree (unit 75a) hand thin, pile, and burn trees less than or equal to 8 inches DBH. Clustered Lady's Slipper: (9 acres within units 51, 52, 54, 55, 66, 67, and 68): Within TES treatment areas, hand thin, pile, and burn trees less than or equal to 8 inches DBH. Within control areas, hand thinning would be allowed, but

Criterion	Actions
	piles must be located outside of the control area. Surface fuels would be manipulated within clustered lady's slipper occurrences to reduce direct impacts from prescribed fire treatments. Constance's Rock Cress: (76 acres within units 64 and 71): Within TES treatment areas, hand thin, pile, and burn trees less than or equal to 8 inches DBH. Piling would occur in designated areas away from sensitive plants.
Fireline	Construct firelines using hand crews or mechanical equipment, as needed, around areas to be underburned, and around machine piles or hand piles. Incorporate existing roads, landings, skid trails, rock fields, bare areas, and other features into containment lines where logical and feasible.
Treatment of Stumps	Pine stumps 14 inches and greater in diameter would be treated with borax within one day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease, in units 45, 46, 49, and 50.

Table 6. Design Criteria for Group Selections

Criterion	Actions
Group size	0.5 acre to 2.0 acres.
Group location	Group selections would primarily be located in CWHR size class 4 stands (average DBH of 11 to 24 inches). Locate groups outside of Riparian Habitat Conservation Areas.
Ground-based Harvesting and Yarding	Mechanical harvesting and whole-tree yarding would be used to remove commercial sawlog and biomass trees. Trees greater than or equal to 10 inches DBH would be removed as sawlog product and trees less than 10 inches DBH would be removed as biomass product. Tops and limbs would be yarded to the landing and removed as a product. Ground-based equipment would be restricted to slopes less than 35 percent. Exceptions may be made for short pitches (less than 100') within the interior of units where slopes exceed these limits. When units have inaccessibly steep inclusions of steeper ground, sawlog and biomass products may be end-lined.
Skyline Harvesting and Yarding	In units 46, 50, 54, 55, 95, and 99a: Skyline yarding would be used to remove commercial sawlogs. Trees greater than or equal to 10 inches DBH would be removed as sawlog product. Harvested trees would be limbed, topped, and this activity slash would be hand piled. Trees less than 10 inches DBH would be hand thinned, piled, and burned post-treatment. In units 2, 4, 5, 21, 27, 28, 29 56, and 59: Whole-tree yarding would be used to remove commercial sawlog and biomass trees. Trees greater than or equal to 10 inches DBH would be removed as a sawlog product. Trees less than 10 inches DBH would be removed as a biomass product. Tops and limbs would be yarded to the landing and removed as a product. Skyline yarding would require one end suspension with full suspension over intermittent and perennial streams. The corridor would not be wider than 20 feet. The width for lateral yarding to the skyline corridor would be 75 feet on either side of the mainline. Lateral yarding would not require lift. Side-hill setups would not be allowed. The top 100 feet of the skyline corridor would be rehabilitated with weed-free straw mulch and native seed.
Diameter constraints	All trees greater than or equal to 30 inches DBH would be retained, except where removal is required to allow for operability. Minimize damage to trees greater than or equal to 30 inches DBH as much as practicable.
Slash treatment / Site Preparation	Based on post treatment evaluations, underburn, jackpot burn, machine pile and burn, and/or hand pile and burn, to treat natural and activity generated fuels, and shrubs.
Regeneration strategy	Regenerate groups with native shade-intolerant conifers, indicative of the ecological habitat type in which the group is located, using a combination of natural and planted seedlings to achieve desired stocking levels. Plantation performance would be monitored after the 1st and 3rd years, and regeneration actions would be undertaken, if needed, to ensure successful regeneration within five years after harvest. Control competing brush and grass by grubbing or mastication, if necessary, to assure survival and growth of conifers.

Criterion	Actions
Residual species preference	Retain all sugar pine tagged as resistant to white pine blister rust. Where black oak is present, retain black oaks greater than or equal to 6 inches DBH.
Residual surface fuels	Maintain adequate cover of surface fuels, litter, duff, and large woody debris to maintain habitat values, reduce potential erosion, and meet soil standards for woody debris and ground cover. Retain surface fuels (less than 12 inches diameter) at a level that would result in projected flame lengths of less than 4 feet under 90th percentile weather conditions. This generally corresponds to approximately 5 tons or less of surface fuels per acre, or a fuel model 8 or 9, depending on the forest type. Fuel model 8 and 9 are representative of the desired condition for surface fuels for fir dominated and pine dominated stands, respectively. Retain Large Woody debris (greater than 12 inches diameter): Where they exist, retain 10 to 15 tons per acre of the largest down logs. Where needed, machine pile and burn extensive areas of deadfall, where feasible, in terms of equipment operability and reduced chance of excessive scorch-related mortality upon burning of these piles. Based on post treatment evaluations, underburn, jackpot burn, machine pile and burn, and/or hand pile and burn to treat natural and activity-generated fuels.
Snag retention	Retain two of the largest snags per acre exceeding 15 inches DBH and 20 feet tall, unless removal is required to allow for operability.
Fireline	Construct firelines using hand crews or mechanical equipment around groups to be underburned and around machine piles or hand piles, as needed. Incorporate existing roads, landings, skid trails, rock fields, bare areas, and other features into containment lines where logical and feasible.
Treatment of Stumps	Under alternative A, Pine stumps 14 inches and greater in diameter would be treated with borax within a day of cutting, to prevent the introduction and spread of *Heterobasidion* root disease, in units 45, 46, 49, and 50.

Notes:

a. Group selections are **not** included in alternative C (non-commercial funding alternative) and alternative D (2001 SNFPA ROD Consistent Alternative).

b. Herbicide treatments are not included in alternatives C and E.

Table 7. Design Criteria for RHCAs

Criterion	Actions
RHCA Equipment constraints	No mechanical equipment operations on slopes steeper than 25 percent. Establish equipment exclusion zones adjacent to stream channels according to Table 9 below. Allow equipment to travel into the outer RHCA zone to harvest trees and bring them to skid trails. Locate skid trails at angles to stream channels that minimize erosion into the channel, and allow skidders to back in to the outer RHCA on these skid trails. To minimize soil displacement, no equipment would be permitted to turn around while off a skid trail in RHCAs. Allow hand thinning and hand piling in areas where equipment is excluded.
Diameter constraints	Within mechanical harvest areas, implement a 20-inch upper diameter limit, except where needed for operability. Minimize damage to trees larger than 20 inches DBH as much as practicable. In equipment exclusion zones, implement an 8-inch upper diameter limit on hand thinning treatments.
Residual species preference	Where present, retain all hardwood and riparian species. Retain the largest, most vigorous dominant and codominant trees to create a residual stand that would be comprised of larger fire-resilient trees.Species preference would be determined by forest type. In general, prefer to retain shade-intolerant species including rust-resistant sugar pine, black oak, ponderosa and Jefferey pine, and Douglas-fir.
Snag retention	Retain the number of snags per acre appropriate for each forest type unless removal is required to allow for operability. In Sierra mixed conifer types and ponderosa pine forest types, retain four of the largest snags per acre. In the red fir forest type, retain six of the largest snags per acre. Snags larger than 15 inches DBH and 20 feet in height would be used to meet this guideline.
Burn constraints	Establish pile burning exclusion zones (Table 10) adjacent to stream channels. Locate burn piles away from riparian vegetation to reduce the potential for scorch where feasible. Active ignition for prescriptive underburning would be minimized within 50 feet of perennial channels and 25 feet of ephemeral and intermittent channels. Backing fires would be used to minimize scorch of riparian vegetation within these buffers.
Fireline	Construct firelines using hand crews around areas to be underburned or pile burned, as needed, Incorporate existing roads, landings, skid trails, rock fields, bare areas, and other features into containment lines where logical and feasible.

Criterion	Actions
Residual surface fuels	Maintain adequate cover of surface fuels, litter, duff, and large woody debris to maintain habitat values, reduce potential erosion, and meet soil standards for woody debris and ground cover. Retain surface fuels (less than 12 inches diameter) at a level that would result in projected flame lengths of less than 4 feet under 90th percentile weather conditions. This generally corresponds to approximately 5 tons or less of surface fuels per acre, or a fuel model 8 or 9, depending on the forest type. Fuel model 8 and 9 are representative of the desired condition for surface fuels for fir dominated and pine dominated stands, respectively. Retain Large Woody debris (greater than 12 inches diameter): Where they exist, retain 10 to 15 tons per acre of the largest down logs. Where needed, machine pile and burn extensive areas of deadfall, where feasible, in terms of equipment operability and reduced chance of excessive scorch-related mortality upon burning of these piles. Based on post treatment evaluations, underburn, jackpot burn, machine pile and burn, and/or hand pile and burn to treat natural and activity-generated fuels.
Fish passage improvement	Reclaim fish passage and habitat by improving or replacing culverts at specific locations where roads cross streams.

Table 8. Scientific Assessment Team (SAT) Guidelines for RHCA Buffer Widths Based on Stream Type (USDA 1999b, page 2-11)

Stream Type	Prescribed Stream Buffer Widths
Perennial, fish bearing[1]	300 feet
Perennial, non-fish bearing[2]	150 feet
Intermittent[3]	100 feet
Ephemeral[3]	100 feet

[1]-Perennial fish bearing streams and lakes.
[2]-Perennial non-fish bearing streams, ponds, wetlands greater than 1 acre, and lakes.
[3]-intermittent and ephemeral streams, wetlands less than 1 acre, and landslides.

Table 8 displays the Scientific Assessment Team guidelines for RHCA buffer widths based on stream type. For the Keddie Ridge Project, the above listed widths would be the maximum buffer width identified for each stream type. Table 9 below displays an additional buffer (inner buffer or equipment exclusion zone) within the RHCA and within the SAT guideline buffer identified above.

For example, there is a perennial fish bearing stream within a treatment unit; a 300 foot buffer is applied. Within that 300 foot buffer, approximately 70 feet from the edge of the active channel, the slope is 22 percent; a 150 foot inner buffer is applied. From the edge of the active channel no equipment can enter the RHCA for 150 feet. Equipment can enter the remaining 150 feet of the 300 foot maximum buffer.

When the slope within the SAT guideline buffer is greater than 25 percent, no mechanical equipment is allowed to enter the RHCA. For example, there is a perennial stream with a treatment unit; a 300 foot buffer is applied. Within that 300 foot buffer, approximately 100 feet from the edge of the active channel, the slope is 32 percent; no equipment is allowed within any portion of the 300 foot buffer.

Table 9. Equipment Exclusion Zones in RHCAs

Stream Type	Slope Class		
	0–15% (feet)	15%–25% (feet)	Greater Than 25%
Perennial, fish bearing	100	150	No mechanical equipment allowed
Perennial, no fish	50	100	No mechanical equipment allowed
Intermittent	25	50	No mechanical equipment allowed
Ephemeral	25	25	No mechanical equipment allowed
Reservoirs/wetlands greater than 1 acre	50	75	No mechanical equipment allowed

Within the SAT guideline buffer, a project specific distance (feet) is applied to the placement of piles for future burning (Table 10). For example, there is an ephemeral stream with a treatment unit; a 100 foot buffer is applied. Within that 100 foot buffer, approximately 70 feet from the active stream channel, the slope is 26 percent. First, no mechanical equipment is allowed within any portion of the 100 foot buffer (Table 9). Second, piles must be placed 15 feet from the center of the stream bed (Table 10).

Table 10. Pile Burning Exclusion Zones in RHCAs

Stream Type	Slope Class	
	0–15% (feet)	Greater Than 15% (feet)
Perennial	25	40
Intermittent	15	25
Ephemeral	15	15
Reservoirs/wetlands greater than 1 acre	15	25
Note: Where feasible, burn piles would not be placed any closer to streams than the distances shown in this table.		

Table 11. Design Criteria for Noxious Weeds

Criterion	Actions
Frequency	1-2 times per season for 2-5 years.
Manual weed treatments	Includes techniques such as hand pulling, digging, cutting (i.e. with a weed whacker), or covering. Would be used to treat small infestations (i.e. less than 50 plants) and as a follow-up method to herbicide or prescribed fire treatments.
Prescribed fire and flaming treatments	Prescribed fire treatments would be conducted in the spring and early summer. Flaming with a propane torch may be used to control weed infestations in areas that are a high risk for spread (i.e. on roads or landings).
Herbicide treatments	Two herbicides would be used to treat noxious weeds: aminopyralid (i.e. Milestone® or an equivalent formulation) and glyphosate (i.e. Accord™ or an equivalent formulation).
Timing of herbicide applications	*Yellow starthistle*: Early spring through summer *Canada thistle*: Early summer and/or fall *Hoary cress*: Early spring to early summer
Aminopyralid treatments	Where: upland infestations Use limitations: aminopyralid applications would be limited to areas that are greater than 15 feet from the water's edge Application: selectively, using a backpack sprayer Rate: 0.05 to 0.11 acid equivalent (a.e.) pounds per acre (lbs/acre)
Glyphosate treatments	Where: Lowland infestations Use limitations: glyphosate applications would be limited to infestations that are between 0 - 15 feet from the water's edge; the one exception to this is the single hoary cress infestation, which will be treated in its entirety with glyphosate Application: wick applicator or backpack sprayer Rate: 1 - 3 acid equivalent (a.e.) pounds per acre (lbs/acre)
Wind speed limitations	Herbicide application using a backpack sprayer would not occur when wind speed exceeds 10 miles per hour or when drift is visually observed.
Herbicide guidelines	All applicable pesticide laws and label restrictions would be followed to ensure human health and safety.
Herbicide Additives [a]	The following additives may be added to herbicide formulations to increase efficacy of treatments: non-ionic modified vegetable oil surfactant [b] (i.e. Competitor® or an equivalent) and water soluble colorant [c] (i.e. Hi-Light™ Blue or an equivalent).

Notes:
[a]. Spray solution additives are mixed with an herbicide solution to improve performance of the spray mixture. Examples include surfactants, wetting agents, sticker-spreaders, or penetrants.
[b.] Surfactants are substances that facilitate and enhance the absorbing, emulsifying, spreading, sticking, wetting, or penetrating properties of herbicides.
[c.] Colorants are added to herbicide mixtures prior to application to help identify the treated area, prevent skips and overlaps, and to help reduce human exposure to recently treated vegetation.
Herbicide treatments are **not** included in alternatives C (non-commercial funding alternative) or E (2004 SNFPA ROD

Criterion	Actions
consistent alternative).	

Table 12. Design Criteria for Access and Transportation

Criterion	Actions
NFS road maintenance	Maintain approximately 50 miles of NFS roads.
NFS road reconstruction	Reconstruct 1.1 miles of NFS roads.
Non-system road reconstruction	Reconstruct 8.1 miles of non-system roads.
Non-system road construction	Construct approximately 6.8 miles of new temporary non-system roads. Decommission these roads upon project completion.
Harvest landings	Landings would be utilized to remove sawlog and biomass products. The Keddie Ridge Project is planned to accommodate product removal with one landing per 40 acres. Per FSH 2409.15, a project should have no more than one landing per 20 acres except when there is a need for more landings to limit resource protection problems. Existing landings shall be reconstructed and utilized considering the location and effects to resources. Would construct new landings where existing landings are not present or are inadequate due to the location and effects to resources. Number and location of landings would be subject to agreement and would conform to direction as specified in FSH 2409.15, SMRs and BMPs. For existing landings supporting cull decks, identify and relocate individual hollow log structures prior to cull deck construction. Relocate hollow logs to forest stand outside of landing disturbance area. Landing spacing for skyline units would be 150 feet. Skyline units may require more landings in order to process biomass. Removal of green trees would occur to allow for temporary non-system road and landing construction.
Notes: a. Road treatments are planned and would be implemented in accordance with the PNF LRMP (USDA 1988) and the Plumas National Forest Public Motorized Travel Management FEIS (USDA 2010a) and ROD (USDA 2010b).	

Table 13. Design Criteria for Watershed Improvements

Criterion	Actions
NFS road improvement	Treatments range from light brushing with no drainage improvements to heavy brushing and large drainage improvements. Drainage improvements may include: outsloping road segments, installing armored rolling dips, or replacing culverts. Improvements to the road drainage system and road surface prism would be considered for 100 miles of road within the watershed analysis area. Rolling dips, which would likely be one of the most commonly prescribed road improvement for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road. This estimate may vary

Criterion	Actions
	depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips would be determined by district watershed staff in order to sufficiently disconnect the road drainage system from nearby stream channels. Refer to appendix C for more details.
NFS road decommissioning	Decomission approximately 0.6 mile of NFS road 28N38A upon project completion.
Non-system road decommissioning	Decomission approximately 0.4 mile of non-system roads upon project completion.
Notes: a. Road treatments are planned and would be implemented in accordance with the PNF LRMP (USDA 1988) and the Plumas National Forest Public Motorized Travel Management FEIS (USDA 2010a) and ROD (USDA 2010b). Watershed improvements are **not** proposed under alternative C (non-commercial funding alternative).	

Alternatives Considered but Eliminated from Detailed Study

Federal agencies are required to rigorously explore and objectively evaluate all reasonable alternatives and to briefly discuss the reasons for eliminating any alternatives that were not developed in detail (40 CFR 1502.14). Public comments received in response to the proposed action provided suggestions for alternative methods for achieving the purposes and needs. Some of these alternatives may have been outside the scope of the need for the proposal, duplicative of the alternatives considered in detail, or determined to be components that would cause unnecessary environmental harm. Therefore, two alternatives were considered, but dismissed from detailed consideration for reasons summarized below:

Alternative F

John Muir Project Alternative

The John Muir Project alternative, alternative F, was suggested during scoping comments. Alternative F is a non-commercial alternative (one that would not sell wood products for timber or biomass) with a 12 inch upper diameter limit and no group selection. This alternative would implement relatively more prescribed fire than thinning, and incorporate some mixed-severity effects into the desired condition for prescribed fire. In this alternative, the priority for treatment would be areas within 100-200 feet of individual homes. On the private lands portion of the 100-200 foot zone around individual homes, the Forest Service should offer to thin small trees and brush for willing homeowners, especially those who cannot afford to do it themselves.

Alternative F was eliminated from detailed study for the following reasons:

- Alternative C (non-commercial funding alternative), an alternative studied in detail, incorporates all live trees greater than or equal to 12 inches DBH being retained throughout all treatments and prescriptions, except to allow for operations.

- Alternatives C and D (2001 SNFPA ROD consistent alternative), two alternatives studied in detail, do not include group selections.
- Prescribed fire treatments in all action alternatives include low to moderate severity underburning. Desired conditions presented in the 2004 SNFPA ROD for fire and fuels management emphasize reducing fire intensity, rate of fire spread, crown fire potential, and mortality of dominant and codominant trees (page 49). The 2004 SNFPA ROD does not include the incorporation of high severity effects within prescribed fire treatments.
- In addition, one of the primary purposes of the Healthy Forest Restoration Act is to "reduce wildfire risk to communities, municipal water supplies, and other at-risk Federal land" (HR 1904, section 2 "Purposes," page 3).
- The Keddie Ridge Project proposes to treat 5,669 acres by constructing DFPZs and AT units, plus 284 acres of group selections. There are approximately 97,376 acres within the identified Keddie Ridge Project area that would remain untreated and provide for a mixed severity effect if a wildfire were to burn these untreated areas.
- The Forest Service doesn't have the authority to conduct activities on private land, unless the Forest Service entered into a cooperative agreement with another entity (Wyden Amendment (Public Law 105-277, Section 323 as amended by Public Law 109-54, Section 434). The Plumas County Fire Safe Council (PCFSC), however, has implemented approximately 294 acres of a combination of hand thinning, piling, and burning; masticating; and some removal of commercial and non-commercial forest products on private lands surrounding homes (appendix F). PCFSC has an application, agreement, and implementation process in effect for Plumas County residents. For more information, visit their website at http://plumasfiresafe.org/.

Alternative G

Alternative G was developed in response to a request from the public that the Forest Service consider an alternative that focuses on non-herbicide treatment methods to control noxious weed infestations in the Keddie Ridge Project area. Alternatives C and E, which include only non-herbicide treatment measures, were also developed in response to this request and were analyzed in detail in Chapter 3. The treatment methods described below were excluded from Alternatives C and E and dropped from detailed analysis due to cost, infeasibility, or failure to adequately contain and control noxious weed infestations within the project area.

Manual Treatment

The manual treatment of all weed infestations was not considered in detail due to cost and feasibility constraints. Manual methods are generally only recommended for small or newly established occurrences. They are most effective on annual species and tap-rooted plants and are considered much less effective for weeds with deep underground stems and roots, such as Canada thistle or hoary cress, due to their ability to re-sprout following treatment (Tu et al. 2001). One example within the Keddie Project area is the single infestation of hoary cress, which was hand-pulled and mowed on an annual basis between 2002 and 2005; over this time period, the infestation increased from an estimated 300 plants to approximately 3,000 individuals.

The number of repeat applications required for manual methods to be effective often ranges from two to four treatments per site per season (Tu et al. 2001), which can significantly increase the estimated per acre cost of treatment. Out of the five weeds that occur within the project area, only two (yellow starthistle and Scotch broom) can be effectively treated with manual methods. Of these, only six sites are considered small (i.e. less than 0.1 acres) and isolated enough to treat with manual methods alone. Under action alternatives A, D, and E, manual methods would be utilized whenever feasible to treat small infestations and as a follow-up within larger infestations.

Biological Control

Biological control methods are used to reduce weed infestations by introducing host-specific organisms that are imported from within the native range of the target species (Holloran 2004). The success of this method is highly dependent upon the biology and ecology of both the target weed species and the biological control agent. Unfortunately, despite numerous attempts, most efforts to control weeds with biological control agents have failed (DiTomaso et al. 2006).

To date, several biological control organisms have been introduced into California in an attempt to control yellow starthistle, Canada thistle, and Scotch broom (Villegas 2009, personal communication); however, very few have established viable populations or shown effective levels of control. In Plumas County, two biological control agents, the false peacock fly and the hairy weevil, were introduced to control yellow starthistle and although they have been observed on flower heads their impact has not been considered adequate for control. At this time, biological control organisms are not considered a viable option for reducing the spread of medusahead or hoary cress (CDFA 2009a).

Plowing, Disking, or Tilling

In agricultural settings, repeated plowing, disking, or tilling can be effective at reducing weed infestations (e.g. Bayer 2000); however, this method is not often recommended in natural areas because it can exacerbate the problem by spreading seed or root fragments to new locations and can severely damage native vegetation (Willard and Lewis 1939 *in* Nuzzo 1997). Within the Keddie Ridge Project area, terrain limitations, as well as rocks, logs, and other native materials, make these treatments impractical for weed control.

Grazing

The use of grazing to control noxious weeds can produce variable results and has been shown to both promote and reduce weeds. Grazing alone will rarely, if ever, completely eradicate infestations (Tu et al. 2001). Grazing animals are not selective and if they are not properly controlled, can cause significant impacts to an ecosystem. Grazing animals can also act as vectors for weed spread as they are moved from site to site. The terrain, as well as the abundance and spatial extent of noxious weed infestations within the Keddie Ridge Project area, makes grazing an impractical option for control.

Comparison of Alternatives

The comparison of alternatives focuses on objectives and issues that provided measureable elements to the proposed action and emphasized the most important environmental effects. These are elements of the ecosystem that can be measured to indicate an increase or decrease in trends in ecosystem health. To compare these elements, measurement indicators were developed to show the differences between the alternatives and provide a clear basis for the decision to be made by the Responsible Official. The measurement indicators are used in the analysis to quantify and describe how well the proposed action and alternatives meet the project objectives.

Table 14 shows the difference between all alternatives by using measurement indicators, Table 15 compares effects of all alternatives by resource, and Table 15a displays acres of treatment for each alternative.

Table 14. Comparison of Measurement Indicators for Each Alternative.

Purpose		Alternative A – Collaborative Alternative (Proposed Action)	Alternative B – No Action	Alternative C– Non-Commercial Funding	Alternative D– 2001 SNFPA Alternative	Alternative E – HFQLG Economic Alternative
Reduce Hazardous Fuel Accumulation	Predicted Flame Lengths (less than 4feet)	100% of stands would meet desired conditions	0% of stands would meet desired conditions	96% of stands would meet desired conditions	96% of stands would meet desired conditions	100% of stands would meet desired conditions
	Fire Type (Surface fire)	100% of stands would meet desired conditions	4% of stands would meet desired conditions	96% of stands would meet desired conditions	96% of stands would meet desired conditions	100% of stands would meet desired conditions
	Predicted Mortality (percent basal area less than 25%)	100% of stands would meet desired conditions	0% of stands would meet desired conditions	96% of stands would meet desired conditions	86% of stands would meet desired conditions	100% of stands would meet desired conditions
Improve Forest Health and Protect and Enhance R5 Forest Service Sensitive Wildlife	Trees Per Acre (Percent retention of trees >20 inches DBH)	All stands would retain 73-100% of trees > 20 inches DBH	All stands would retain 100% of trees > 20 inches DBH	All stands would retain 100% of trees > 20 inches DBH	All stands would retain 100% of trees > 20 inches DBH	All stands would retain 73-100% of trees > 20 inches DBH
	Basal Area Per Acre (less than or equal to 150 ft^2)	68% of stands would meet desired conditions	7% of stands would meet desired conditions	36% of stands would meet desired conditions	11% of stands would meet desired conditions	61% of stands would meet desired conditions

Chapter 3. Affected Environment and Environmental Consequences

This chapter describes aspects of the environment likely to be affected by the proposed action and alternatives. Also described are the environmental effects (direct, indirect, and cumulative) that would result from undertaking the proposed action or alternative. Together, these descriptions form the scientific and analytical basis for the comparison of effects in Chapter 2.

The following resource specialist analyses are incorporated by reference: Keddie Ridge Hazardous Fuels Reduction Project Forest Vegetation, Fire, Fuels, and Air Quality Report (Ryan Tompkins and Ryan Bauer)(USDA 2011a); Keddie Ridge Hazardous Fuels Reduction Project Wildlife Biological Assessment/Biological Evaluation (Chris Collins)(USDA 2011b); Management Indicator Species Report for the Keddie Ridge Hazardous Fuels Reduction Project (Chris Collins)(USDA 2011c); Keddie Ridge Hazardous Fuels Reduction Project Wildlife Supplemental Information Migratory Birds Report (Chris Collins)(USDA 2001d); Keddie Ridge Hazardous Fuels Reduction Project Watershed Report (Kelby Gardiner)(USDA 2011e); Keddie Ridge Hazardous Fuels Reduction Project: Biological Evaluation of Potential Effects to Threatened, Endangered, and Sensitive Plant Species (Michelle Coppoletta)(USDA 2011f); Keddie Ridge Hazardous Fuels Reduction Project Heritage Resource Inventory Report ARR# 02-28-2011 (Cristina Weinberg, January 2011)(USDA 2011g).

Past, Present and Reasonably Foreseeable Actions

According to the Council on Environmental Quality (CEQ) National Environmental Policy Act (NEPA) regulations, “cumulative impact” is the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such actions (40 CFR §1508.7).

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.”

The cumulative effects analysis in this EIS is also consistent with Forest Service National Environmental Policy Act (NEPA) Regulations (36 CFR §220.4(f)) (July 24, 2008), which state, in part:

> “CEQ regulations do not require the consideration of the individual effects of all past actions to determine the present effects of past actions. Once the agency has identified those present effects of past actions that warrant consideration, the agency assesses the extent that the effects of the proposal for agency action or its alternatives will add to, modify, or mitigate those effects. The final analysis documents an agency assessment of the cumulative effects of the actions considered (including past, present, and reasonable foreseeable future actions) on the affected environment. With respect to past actions, during the scoping process and subsequent preparation of the analysis, the agency must determine what information regarding past actions is useful and relevant to the required analysis of cumulative effects. Cataloging past actions and specific information about the direct and indirect effects of their design and implementation could in some contexts be useful to predict the cumulative effects of the proposal. The CEQ regulations, however, do not require agencies to catalogue or exhaustively list and analyze all individual past actions. Simply because information about past actions may be available or obtained with reasonable effort does not mean that it is relevant and necessary to inform decision making. (40 CFR §1508.7)”

In determining cumulative effects, the past, present, and future actions displayed in appendix F were added to the direct and indirect effects of the proposed action and alternatives.

Affected environment sections have been divided by resource areas, where as environmental consequence sections have been divided by resource areas and then by alternative, where is some cases, action alternatives are grouped.. Further, effects analyses that are required by law are discussed per alternative.

Forest Vegetation, Fuels, Fire, and Air Quality

Introduction

Ecologically, the dynamics between vegetation and fire and fuels are inherently linked because vegetation type, structure, and development have a profound effect on fuel accumulations and fire behavior, and conversely, fuel accumulations and fire behavior can have a profound effect on vegetation establishment, development, and structure. Consequently, forest vegetation, and fuels and potential fire behavior are examined with an integrated approach for the purposes of this analysis. This section includes complete discussions of possible effects of the proposed project and alternatives and presents a summary of the Forest Vegetation, Fuels, Fire, and Air Quality Specialist Report for the Keddie Ridge Hazardous Fuels Reduction Project which is on file at the Mt. Hough Ranger District office and available upon request.

The forested landscape in the Keddie Ridge Project area consists primarily of pine-dominated Sierra mixed conifer forests with some ponderosa pine, true fir forests, and plantations established over the last 40 years in burned areas and clear-cut timber harvest units. Forests in the project area range from 3,000 feet to 7,500 feet in elevation with an annual precipitation ranging from 30 to 50 inches.

The Keddie Ridge Project area lies along the crest of the Northern reach of the Sierra Nevada range. These forests are within the transition zone—an ecological zone used to describe the transition between the wet productive westside forests of the Sierra Nevada and the relatively dry, less productive eastside forests of the Sierra Nevada (USDA 1999a, b). Consequently, the forests in the project area tend to be drier and occur on less productive sites. The Forest Survey Site Class (FSSC) in the project area ranges from 4 to 7 (based on an index where FSSC 7 represents the least productive site class); however more than half of the project area is classified as Forest Survey Site Class 6 which represents a mean annual increment – growth rate – of 20 to 46 cubic feet per acre per year (USDA SCS 1988).

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

The Keddie Ridge Hazardous Fuels Reduction Project is designed to fulfill the management direction specified in the 1988 Plumas National Forest Land and Resource Management Plan (PNF LRMP) (USDA 1988), as amended by the Herger-Feinstein Quincy Library Group (HFQLG) Final Supplemental environmental impact statement (FSEIS) and Record of Decision (ROD) (USDA 1999a, b; USDA 2003a, b), and the Sierra Nevada Forest Plan Amendment (SNFPA) FSEIS and ROD (USDA 2004a, b). Fuel and vegetation management activities are designed to comply with the standards and guidelines as described in the SNFPA FSEIS and ROD (USDA 2004a, b).

National Forest Management Act

The National Forest Management Act (NFMA) of 1976, including its amendments to the Forest and Rangeland Renewable Resources Planning Act of 1974 state that it is the policy of the Congress that all forested lands in the National Forest System be maintained in appropriate forest cover with species of trees, degree of stocking, rate of growth, and conditions of stand designed to secure the maximum benefits of multiple use sustained yield management in accordance with land management plans. Both acts also state “insure that timber will be harvested from National Forest System land only where – (ii) there is assurance that such lands can be adequately restocked within five years of harvest.”

Plumas National Forest Land Management Plan (1988) as Amended by the Herger-Feinsten Quincy Library Group FSEIS and ROD (1999, 2003) and the Sierra Nevada Forest Plan Amendment FSEIS and ROD (2004)

The desired condition as described in Alternative 2 of the HFQLG Final Environmental Impact Statement (USDA 1999a) is an “all-aged, multistory, fire-resistant forest,” of open forest stands dominated by large, fire tolerant trees with crowns sufficiently spaced to limit the spread of crown fire. Riparian ecosystems would be resilient to impacts caused by naturally occurring disturbance processes such as wildfire, flood, and drought.

The 2004 SNFPA provides management direction for the HFQLG pilot project area in appendix E of the Record of Decision (USDA 2004b). Appendix E directs the Plumas National Forest to “implement the HFQLG Forest Recovery Act Pilot Project, consistent with the HFQLG Forest Recovery Act and Alternative 2 of the HFQLG EIS. The HFQLG Forest Recovery Act Pilot Project is designed to test and demonstrate the effectiveness of certain fuels and vegetation management activities in meeting ecologic, economic, and fuel reduction objectives. Fuels and vegetation management activities include constructing a strategic system of defensible fuel profile zones (DFPZs), group selection, and individual tree selection. A management program for riparian areas is also included in the pilot project.”

Sierra Nevada Forest Plan Amendment: Final Supplemental Environmental Impact Statement Record of Decision: Forest-wide Standards and Guidelines (2004)

The standards and guidelines for fuels and vegetation management projects for the HFQLG Pilot Project are shown in Table 2 of the 2004 SNFPA Record of Decision (USDA 2004b). This table includes direction for designing and implementing fuels and vegetation management activities within the various land allocations of the HFQLG pilot project area for the life of the pilot project.

Effects Analysis Methodology

Geographic and Temporal Bounds

The approximate 106,000-acre boundary of the watersheds in the Keddie Ridge Project area forms the geographic boundary of the analysis area used to analyze the direct, indirect, and cumulative effects on forest vegetation and fuels and fire. The analysis area is comprised of twelve watersheds: Taylorsville, Mt. Jura, Peters Creek, Upper Cooks Creek, Lower Cooks Creek, Upper Wolf Creek, Upper Wolf Creek-Haun’s Creek, Lower Wolf Creek, Lower Wolf Creek-Greenville, Round Valley, Crescent Mills, and Indian Falls. The analysis area includes the vegetation occurring within the treatment areas as well as the vegetation outside of the treatment areas within the affected watersheds. The analysis considers the twelve watersheds because, when combined, they represent the furthest measurable extent that effects on forest vegetation would occur as a result of implementing any of the proposed alternatives. With respect to fire, these watersheds, as a group, are geographically bounded by high-elevation ridgelines that are sparsely vegetated in places. Because of this, most of the fires that have occurred in these watersheds have been managed at the watershed level or smaller. Ecologically, the dynamics between vegetation and fire and fuels are inherently linked; vegetation treatments (and absence thereof) have a profound effect on fuels accumulations and fire behavior, and conversely, fire has a profound effect on vegetation establishment and development.

The analysis area considers this relationship on the landscape level by including the vegetation and past large wildfires and contains all National Forest System lands available for and subject to proposed treatments under the Keddie Ridge Project, as well as the vegetation within the watersheds outside treatment areas. This allows for a congruent analysis of forest vegetation, fuels, and fire at the stand and landscape levels.

The direct, indirect, and cumulative effects analyses are based on a temporal scale. Documented past projects including timber harvesting, wildfires, watershed improvements, and other activities described in appendix F ranging as far back as 1980 were considered past actions within the analysis area. In a broader sense, current vegetation structure and composition reflects the historical management regimes prior to 1980. This vegetation structure and composition includes attributes of the current landscape including existing vegetation types, fuel treatments, burned areas, past sanitation harvest, and plantations.

For the purpose of the vegetation analysis, the temporal bounds include a 30-year horizon for future effects. Within 30 years, the treated stands would approach current levels of stocking and would approach the typical entry cycle for managed stands. This timeframe allows for examining general trends and trajectories of stand development under no further management beyond those documented in “Appendix F: Past, Present, and Reasonably Foreseeable Future Actions,” which is located in this EIS.

The potential fire behavior and effects of alternatives were modeled pre treatment and post-treatment, with the latter reflecting treatments after completion. Fuel treatments are expected to remain effective for at least 10 years—this is based on experience with existing fuel treatments on the Mt. Hough Ranger District. Fuel treatments would likely require entry for burning and other maintenance prior to the 30-year horizon modeled for tree stand growth (USDA 2004a). Future maintenance activities are discussed in appendix F (Past, Present, and Reasonably Foreseeable Future Projects of this document).

With respect to air quality; the towns, communities, and national parks within 20 miles of the project area boundary are listed in Table 22. It is important to note that unknown or unanticipated future wildfires, disease outbreaks, or mortality may occur in the analysis area prior to completion of implementation of this project—these potential future disturbance events are not included as part of this analysis.

Analysis Methodology

Field inventories were conducted to measure attributes of existing vegetation in the analysis area. Stands in the analysis area were inventoried using the Common Stand Exam protocols for the Pacific Southwest Region (U.S. Department of Agriculture [USDA] Forest Service Region 5). These stands are representative of the analysis area and the areas to be treated in all action alternatives. Data was collected on live and dead trees and fuels.

For analysis purposes, the stand data was loaded into the Forest Vegetation Simulator, a forest growth model that predicts forest stand development (Dixon 2002). The model was used to quantify existing stand conditions and to predict the effect of alternative treatments on forest development. Stand growth, mortality, regeneration, and development by stand were simulated to predict the effects of treatments over time. The FVS model output predicts average stand conditions and attributes by stand. The stand attributes analyzed include trees per acre, basal area, quadratic mean diameter, stand density index, canopy cover, and species composition. Model outputs by stand were utilized to examine the effects of treatment over the larger landscape scale. Model outputs have unknown variances that may sometimes be large; however, this is normal for modeling efforts, and model outputs are best evaluated in a relative rather than an absolute sense. In addition, model simulations have limited capacity to predict mortality due to drought or insect and disease outbreaks. Considering this, model outputs such as stand density and basal area provide useful metrics for determining relative risk of these effects. This further underscores that interpretation of model outputs are best evaluated in a relative sense in conjunction with professional judgement, firsthand knowledge of stand conditions, forest health evaluations, and pertinent scientific research, studies, and literature. For more information regarding FVS modeling by alternative, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C.

A Geographic Information System (GIS) was used to analyze forest vegetation on the landscape scale for the analysis area. Forest-wide vegetation typing into California Wildlife Habitat Relationships (CWHR) classifications (Mayer and Laudenslayer 1988) was done for the Plumas-Lassen Administrative Study in 2002 (Vestra 2002). This vegetation layer was updated after the Moonlight Fire of 2007, which affected a small portion of the analysis area. The Vestra vegetation data also did not include a portion of the analysis area. The HFQLG 2005 Vegetation Mapping Project mapped areas on the Plumas National Forest not covered by Vestra. These data were combined in a GIS to provide a complete map of the existing vegetation within the analysis area. All vegetation information is displayed using CWHR vegetation typing and serves as the baseline acres for analysis. The distribution of CWHR size class and density was analyzed relative to the stand-level effects modeled by CWHR size class. Other sources of information used in the assessment of effects were aerial photos, data generated from common stand exam plots, and field reconnaissance.

Fire Behavior and Effects

The effects of all alternatives were analyzed at the stand and landscape level using widely accepted models: 1) Fire Family Plus and 2) Fire and Fuels Extension of the Forest Vegetation Simulator (FFE). The output data reflects fire modeling assumptions (weather, fuel model characteristics, and spatial variability) and variability within the common stand exam plots. These models are extensively described and documented in their accompanying user manuals; general assumptions and outputs of these models are summarized below:

1. Fire Family Plus (Main et al. 1990): Fire Family Plus is a widely used software program for summarizing and analyzing historical daily fire weather observations and computing fire danger indices based on the National Fire Danger Rating System (NFDRS). For this analysis, the modeling of potential fire behavior was done under 90th percentile weather conditions (Table 16) that were calculated using Fire Family Plus (Main et al. 1990). The 90th percentile weather is defined as the severest 10 percent of the historical fire weather conditions occurring during the fire season. Ninetieth percentile weather conditions are the specified weather standard for fuel treatment design (USDA 2004b). Weather data used in fire modeling were obtained from the Quincy, Pierce, and Cashman Weather Stations, which are the closest and most representative weather stations to the analysis area.

The Pierce and Cashman Weather Stations are located on south-facing open slopes in areas that typically reflect the hottest, driest, and windiest weather conditions.

2. Fire and Fuels Extension (Reinhardt and Crookston 2003): The Fire and Fuels Extension (FFE) of the Forest Vegetation Simulator (FVS) were used to model predicted fuel loading and potential fire behavior. Modeling was done using the 90th percentile weather calculated using Fire Family Plus and displayed in Table 16. The Fire and Fuels Extension utilizes stand specific surface fuel and stand inventory data and was used to model and assess the effects of different treatments on potential flame length, probability of torching, potential fire type, and predicted tree mortality at the stand level. The output data reflect fire modeling assumptions (weather, fuel model characteristics, and spatial variability) and variability within the Common Stand Exam plots. Model outputs have unknown variances that may sometimes be large; however, this is normal for modeling efforts, and model outputs are best evaluated in a relative rather than an absolute sense. Fuel model selection logic based on expert opinion (Duncan, pers. comm., 2010) and time-since-disturbance was developed similar to Collins et al (In press) to determine fuel model succession post-treatment. For more information regarding FVS modeling by alternative, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C.

Table 16. Fire Weather Parameters Used in Fire Modeling

Weather Variable	Value	Weather Variable	Value
Weather Station Names and Numbers Years 2000-2010	Quincy (#040910) , Pierce (#040915), and Cashman (#040916)	1-hour fuel moisture	1.0%
		10-hour fuel moisture	2.0%
Time of Year	June 1 to September 15	100-hour fuel moisture	5.5%
Temperature (Fahrenheit)	93°	1,000-hour fuel moisture	6.0%
Relative Humidity	10%	Herbaceous fuel moisture	29%
Probable maximum 1 minute 20-foot wind speed[a]	9 mph	Woody fuel moisture	69%

Measurement Indicators

Forest Vegetation: Stand Structure and Composition and Landscape Heterogeneity

The effects of treatment on stand structure, compositional structure, and landscape structure of forest vegetation are evaluated for each alternative. These measurement indicators focus on residual post-treatment attributes of forest vegetation structure, density, species composition, and landscape diversity and heterogeneity as residual post-treatment conditions are the best indicator of how well desired conditions as described in Chapter 1 would be met for the project purposes and needs.

Stand Structure—Stand structure is analyzed using three measures of stocking and density: (1) trees per acre and their distribution by diameter class, (2) basal area per acre, and (3) relative stand density.

Table 17. Diameter Class and Tree Size by Forest Product

CWHR Tree Size	Sapling to Pole Size Trees	Small-sized trees	Intermediate-sized trees (small to medium)	Medium to Large-sized trees
Forest Product	Biomass Trees	Sawlog Trees		Reserve Trees
Diameter Class	0-10 inches DBH	10-20 inches	20-30 inches	+30 inches
Note: DBH = diameter at breast height				

*Trees per Acre and Their Distribution by Diameter Class***:** The number and distribution of trees per acre by diameter class (Table 17) is an important unit of measure because it shows the effect of treatments on different size trees. High density stands also slow the rate of fire line construction by hand crews and mechanical equipment. The four diameter classes are based on diameter classes for forest products (biomass and sawlog products), ecological importance for fire behavior and wildlife habitat, and guidelines for reserve trees upon which silvicultural prescriptions are based. The sawlog-sized trees are split into two 10-inch diameter classes to track the effect of treatments on the intermediate-sized tree class as described in the GTR 220 (North et al. 2009). The percent reduction of trees per acre is used to show the effects of treatments on reducing stocking and the percent retention of trees greater than 20 inches in diameter is used to show the effects of treatments on the intermediate and large tree size classes which are valued for ecological structure and function for wildlife habitat.

Basal area per acre: Basal area per acre is “the cross-sectional area of all stems in a stand measured at breast height and expressed per unit land area” (in this case, per acre) (Helms 1998). Basal area per acre is commonly used as a measure of stand density. This measure has been used by Oliver (1995) to describe the threshold for ponderosa pine (150 square feet per acre), above which bark beetle related mortality is expected to occur. This threshold is related to Sartwell’s work (Sartwell 1971, Sartwell and Steven 1975, Sartwell and Dolph 1976) with mountain pine beetle outbreaks as described by Powell (1999) where these “outbreaks could be attributed to two primary factors: second-growth ponderosa pine stands were even-aged and ecologically simplified when compared with the uneven “virgin” forest; and man’s intentional suppression of wildfire effectively removed an important landscape-level thinning agent, which in turn caused an unnatural accumulation of stand density (basal area) as compared to virgin conditions.” Both of these conditions occur within the Keddie Ridge Project landscape as described in the affected environment

For true fir stands, Oliver’s research (1988) found that “plots with 200 square feet per acre or more basal area suffered the bulk of the mortality.” This may allow for leaving slightly higher densities in pure true fir stands, however, Powell (1999) recommends for mixed species stands (which are prevalent in the analysis area) that the “lowest stocking-level recommendations could be selected” because other species (such true fir species) would develop acceptably under the lower densities established for the limiting species (pine species). “This is the strategy recommended by Cochran and others (1994).”(Powell 1999)

In addition, basal area per acre has also been used by Landram (2004) to develop insect risk thinning guidelines for the eastside, transition, and westside zones of the Plumas National Forest. For the transition zone (where the Keddie Ridge Project is primarily located), the insect risk thinning guides for the Plumas suggest thinning to 150 square feet per acre. For more information regarding basal area and forest health, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Relative stand density: The concept of stand density index was first developed for even-aged stands by Reinecke (1933) to compare "the density of stocking of various stands." The relative density concept describes a stand's density relative to the maximum possible density and may serve as a proxy for a stand density relative to its carrying capacity. In general, the concept of stand density as a measure has been further developed for forest management applications for both even-aged and uneven-aged stands (Curtis 1970; Drew and Flewelling 1977, 1979; Long 1985; Long and Daniel 1990; Helms and Tappeiner 1996; Jack and Long 1996; Powell 1999; Woodall et al. 2002).

A relative density between 55 and 60 percent has been described as the lower limit of the "Zone of Imminent Competition Mortality" above which trees begin to die due to competition related stress (Drew and Flewelling 1977, 1979; Long 1985; Long and Daniel 1990; Smith et al. 1997; Powell 1999; Long and Shaw 2005). For the purpose of this analysis, 60 percent was used as a measure of the onset of competition-related mortality because stress induced by competition increases tree susceptibility to drought, insects, disease, and fire. This threshold serves as an appropriate measure for forest health because stands managed below this threshold are less likely to incur mortality due to the agents mentioned above.

The desired relative densities immediately post-treatment are between 25 and 40 percent, the lower bounds of which correspond with the onset of competition and crown closure. These levels are substantially below the threshold of imminent competition mortality, and treatments within the desired range should have a reasonable "lifetime" before reaching densities at which mortality is expected to occur. Desired relative densities within 20 to 30 years would be below the 60 percent threshold of imminent competition mortality (Blackwell 2004) as this longer time frame would be representative of a reasonable cutting or entry cycle.

Reinecke (1933) described a maximum stand density of 750 for mixed conifer stands in California. The calculation of this maximum stand density is largely dependent on the mix of species. A more site-specific maximum stand density was calculated for each stand using the Forest Vegetation Simulator (FVS), which calculates maximum stand density weighted by the "proportion of basal area each individual species represents in the stand" (Dixon 2002). This may be a more appropriate measure of maximum stand density as it considers site-specific species composition reflected in the existing condition. For the purpose of this analysis, relative density based on the maximum stand density index as calculated by FVS is used. For more information regarding relative stand density, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Compositional Structure—Compositional structure is measured by calculating the percent of species composition pre and post-treatment. Species composition is analyzed because silvicultural prescriptions, particularly group selection treatments, may have an effect at the stand level on differing species dependent on shade tolerance and species biology. Residual species composition post-treatment is an important measure because these trees represent the seed bank of the future, which is one factor that affects species diversity over time. The shift in species composition in the northern Sierra Nevada forests from shade-intolerant species, such as ponderosa pine, to shade-tolerant species, such as white fir, has been well documented in scientific literature (McKelvey and Johnston 1992, Skinner and Chang 1996, Ansley and Battles 1998). Therefore, treatments that improve the percentage of pine species in forested stands would be beneficial. Percent change in pine species composition is used to show the effects that treatments within the alternatives would have on species composition. For more information regarding desired species composition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Landscape Structure— For the purposes of this analysis, landscape structure refers to the distribution of relative successional (seral) stages on the landscape, and the relative distribution of closed-canopy and open canopy stands. This is an important indicator because it may be used as a measure of landscape heterogeneity and diversity, and as a measure of cumulative effects to forest vegetation on the landscape scale. Landscape structure is measured by calculating the distribution of these seral stages within the vegetation analysis area. The relative distribution of seral stages within the landscape is measured by using CWHR size class as a proxy for seral stage. Table 18 displays the CWHR tree size and density class categories. CWHR size class serves as an effective proxy for seral stage because it classifies forest vegetation by ranges of average tree size which represent discrete developmental stages of tree growth. CWHR density class serves an effective proxy for open and closed-canopy conditions because it classifies canopy cover. In addition, this allows for a congruent analysis of effects on forest vegetation and wildlife habitat. Forest stands were aggregated by CWHR size class because the proposed treatments, stand structure, and effects of treatments on stand structure would not substantially vary by forest vegetation type (as classified by CWHR habitat type). For more information regarding desired landscape structure and heterogeneity, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A and Appendix C.

Table 18. CWHR Tree Size and Density Class Crosswalk with Seral Stage and Canopy Closure Condition

CWHR Tree Size Categories				CWHR Density Class Categories			
CWHR Size Class	**Tree Sizes (average)**	**Description**	**Seral Stage**	**CWHR Density Class**	**Tree Canopy cover**	**Description**	**Canopy Conditions**
1	< 1” DBH	Seedlings, but definite forest habitat	Early Seral	n/a	< 10%		Open canopy Stands
2	1 -6 “ DBH	Sapling		S	10 - 24%	Sparse	
3	6 -11” DBH	Pole-sized tree		P	25 - 39%	Open	
4	11 – 24” DBH	Small Tree	Mid-seral	M	40 - 60%	Moderate	Closed-canopy Stands
5	> 24” DBH	Medium/Large tree	Later Seral	D	> 60%	Dense	
6	> 24” DBH	Multilayered canopy with dense cover		n/a	> 60%		

Fuels and Potential Fire Behavior and Effects

The measurement indicators for potential treatment effects on fuels, potential fire behavior, and severity include: (1) flame length, (2) probability of torching, (3) fire type, and (4) predicted percent mortality. These indicators are described below. For more information regarding fuels reduction, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix B.

Flame Length (feet): The predicted length of flame measured in feet. Flame length is influenced in part by fuel type, fire type (surface or crown fire), and weather conditions. Together, flame length and fuel type influence the rates at which firelines can be safely and effectively constructed by different fire resources, including fire fighters, bull dozers, and aerially delivered fire retardant (Table 19). Increased flame lengths can increase the likelihood of crown fire and the amount of suppression resources (fire fighters, fire engines, and aircraft) needed to contain a wildfire. Flame lengths above 4 feet may present serious control problems—they are too dangerous to be directly contained by fire crews (Schlobohm and Brain 2002; Andrews and Rothermel 1982). Flame lengths over 8 feet are generally not controllable by ground-based equipment or aerial retardant and present serious control problems including ignition of multiple spot fires and uncontrollable crown fire activity. The 2004 SNFPA ROD provides direction that the desired condition for fuel treatments include flame lengths at the head of the fire less than 4 feet (USDA 2004b).

Table 19. Relationship between Flame Length and Potential Success of Active Suppression

Flame Length	Description
Less than 4 feet	Fires can generally be attacked at the head or flanks by firefighters using hand tools. A hand line should hold the fire.
4 to 8 feet	Fires are too intense for direct attack at the head with hand tools. A hand line cannot be relied on to hold the fire. Bulldozers, engines, and retardant drops can be effective.
8 to 11 feet	Fire may present serious control problems: torching, crowning, and spotting. Control efforts at the head will probably be ineffective.
Greater than 11 feet	Crowning, spotting, and major fire runs are probable. Control efforts at the head of the fire are ineffective.
Source: NWCG 2004	

Probability of Torching : The potential probability of torching occurring under 90th percentile weather conditions as predicted by FFE. This is the probability of finding an area of the stand where torching can occur. A torching situation is generally defined as one where tree crowns of large trees can be ignited by a surface fire or flames from burning crowns of small trees that reach the larger trees. Probability of torching is the proportion of areas where trees are present and torching is possible (Rebain et al. 2010).

Fire Type (Surface or Crown Fire): The predicted fire type (surface or crown fire) occurring under 90th percentile weather conditions as predicted by FFE. Crown fire includes both active and passive crown fire (Stratton 2004). Fire type will affect the difficulty of controlling a fire, fire fighter and public safety, and fire-related tree damage and mortality. Generally speaking, it is more difficult and more expensive to safely contain crown fires because they burn with high heat intensity and move extremely quickly. Crown fires typically lead to more tree damage than surface fires. Surface fires, with flame lengths less than 4-feet, are easier to safely contain and result in less tree damage than a crown fire (Table 19). For this reason, surface fires with flame lengths less than 4 feet within treated stands are the desired post-treatment condition.

Predicted Percent Mortality: The potential tree mortality as measured by the percent of basal area that would be killed in a fire event occurring under 90th percentile weather conditions as predicted by FFE (Reinhardt and Crookston 2003, Rebain et al. 2010). “The probability of mortality is based on bark thickness and percent crown volume scorched, which are derived from scorch height, tree height, crown ratio, species, and tree diameter” (Carlton 2004) . The mortality calculation uses established calculation methods (Reinhart et al. 1997).

Air Quality

The measurement indicator for alternatives effects on air quality include smoke and dust emissions from proposed treatments.

Predicted Particulate Matter (PM) in Tons: Predicted amounts of particulate matter emitted from the project is measured by PM10 (county wide) and PM 2.5 (Portola Valley only) as forest management activities such as pile burning and underburning contribute to these levels.

Types and Duration of Effects

Direct Effects

These are effects on forest vegetation, fuels, and air quality that are directly caused by treatment implementation or, as with Alternative B (no action), a lack of treatment.

Indirect Effects

These would be effects on forest vegetation and fuels, potential fire behavior, and air quality that are in response to the direct effects of treatment implementation or, as with Alternative B (no action), a lack of treatment.

Duration of Effects

Direct effects would likely be limited to the project implementation phase. Indirect effects would last beyond the implementation period and occur within the temporal bound of the cumulative effects analysis described above in “Geographic and Temporal bounds”.

Cumulative Effects Analysis

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions.

Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.

Affected Environment

Forest Structure, Composition, Fuels, and Fire

As with many areas in the Sierra Nevada, the landscape in the analysis area has been heavily influenced over the last 150 years by past management activities that include mining, grazing, timber harvesting, fire exclusion, large high-severity fires (Young 2003; Beesley 1996; McKelvey and Johnston 1992), and more recent drought-related mortality during the late 1980s and early 1990s (Guarin and Taylor 2005; Ferrell 1996; Macomber and Woodcock 1994).

Past harvest activities on the Keddie Ridge Project landscape were primarily focused on overstory removal and sanitation or salvage harvest, with a shift toward even-aged systems in the 1980s. Past use of these harvest systems is consistent with well-documented overall management practices that occurred over vast areas of the Sierra Nevada during the 20th century (UC 1996; Leiberg 1902). With respect to the removal of ponderosa and Jeffrey pine, and the resulting increase in the occurrence of white fir in the watershed of the North Fork of the Feather River, John Leiberg (1902) noted:

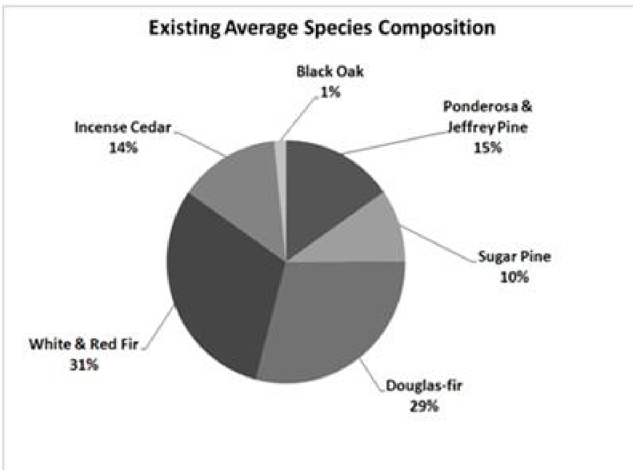

Figure 1. Existing Average Species Composition

> *"It [yellow pine] has been more exhaustively logged than any other species in the type except the sugar pine, and the restocking has not kept pace with the cutting," (page 29)* and
> *"White fir is increasing its ratio in the restocking, partly at the expense of the yellow pine, partly as an offset to a lessened percentage of sugar pine. On the Pacific side of the main range there is a steady increase of the species, both in reforestation on the logged areas and on the tracts denuded by fire. Its [white fir] increase throughout the region examined is due to exhaustive logging of yellow and sugar pine and sparing of white fir" (page 50).*

Currently, shade-tolerant species dominate most of the analysis area stands; however conditions range stand by stand which have varying levels of shade-tolerant versus shade-intolerant species. Those stands on lower elevation south and west facing slopes have greater amounts of shade-intolerant species, yet many mixed species stands have very high proportions of shade-tolerant species. Figure 1 displays the existing average species composition for all stands. Currently, shade-tolerant species including white fir, incidental amounts of red fir, Douglas-fir, and incense cedar account for 74 percent of tree species present in project area stands. Desired shade-intolerant tree species such as black oak, ponderosa pine, Jeffrey pine, and sugar pine only account for 26 percent of the trees species present in project area stands.

Past harvest activities described above have resulted in 1) the reduction of large dominant and codominant overstory trees, 2) the retention of smaller diameter intermediate and suppressed trees and 3) a shift in species composition from shade-intolerant pine dominated stands to shade-tolerant, white fir dominated stands; all of which have largely decreased landscape level forest heterogeneity (diversity) (McKelvey and Johnston 1992). In addition, a near absence of landscape level, low-intensity surface fires has contributed to increased stand densities in smaller diameter classes, particularly in shade-tolerant species (Skinner and Chang 1996).

At the stand level, similar to what has occurred at the landscape level, the combination of past management activities, fire exclusion, and extensive drought-related mortality has created relatively homogeneous areas typified by small even-aged trees existing at high densities (Oliver et al. 1996). High-density stands are also more susceptible to density-dependent mortality driven by drought and insect and disease infestations (Cochran et al.1994; Guarin and Taylor 2005; Macomber and Woodcock 1994, Powell 1999). Extensive drought in the late 1980s and early 1990s, combined with high stand density, resulted in extensive mortality of white fir (Guarin and Taylor 2005; Ferrell 1996; Macomber and Woodcock 1994). Much of this material has fallen over in the last 20 years and become dead and down fuel. The high densities of small trees and high fuel loads contribute to:

- overstocked stand conditions in which trees become stressed due to competition for water, light, and nutrients; this can lead to a higher potential for mortality due to drought, insects, or disease (Powell 1999; Ferrell 1996; Guarin and Taylor 2005; Fettig 2007);
- Conditions that favor the recruitment of shade-tolerant species such as white fir, which promotes a shift in species composition from pine-dominated to fir-dominated forests (Oliver et al. 1996; McKelvey and Johnston 1992); and
- large accumulations of ground fuels, ladder fuels, and canopy fuels which increase the potential for stand-replacing, high-severity fire events (Weatherspoon and Skinner 1996).

As a result of past management activities described above, conditions across the Sierra Nevada have been described as “generally younger, denser, smaller in diameter, and more homogeneous” (McKelvey et al. 1996); this condition is typical of forests in the analysis area. Such conditions are best characterized by California Wildlife Habitat Relationship (CWHR) size class 4 where diameter at breast height (DBH) ranges between 11 and 24 inches. Analysis of CWHR size class distribution for forest types in the analysis area shows a relative overabundance of CWHR size class 4, indicating a departure from desired distributions of seral stages (Figure 2). Taylor (2004) observed in his study of the Lake Tahoe Basin that “pre-settlement forests were more structurally diverse than contemporary forests” and consisted of larger trees at lower densities — the would be more characteristic of open canopy, later seral stands such as

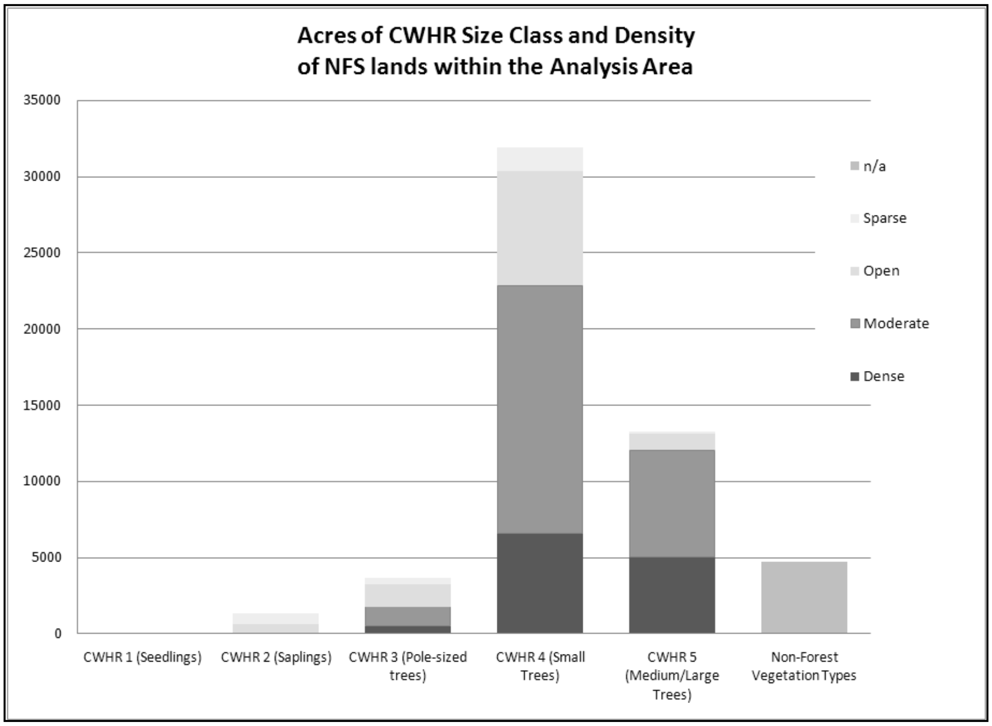

Figure 2. Existing Size Class and Density Distribution of Forest Vegetation Occurring on NFS Lands within the Analysis Area

CWHR5P. In contrast, the relative dominance of CWHR size class 4 likely developed as a result of overstory removal and salvage harvest systems in concert with fire suppression policies.

Because such stand structure has increased vulnerability to high-severity fires, insect outbreaks, and landscape level drought-induced mortality, a homogenous (same species or structure) occurrence of this seral stage across the landscape is unstable (McKelvey and Johnston 1992, Millar et al. 2007). A more diverse distribution of seral stages, characterized by heterogeneous stand structures, may be more resilient to disturbance events such as fire, drought, and insect and disease infestations and more characteristic of desired conditions (Stephens and Fule 2005, Millar et al. 2007, Collins and Stephens 2010). For more information regarding desired conditions for forest and landscape structure, density, and heterogeneity, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Fire Regimes and Condition Class

Historically, the average number of years between fires in the mixed conifer forests adjacent to the analysis area has been reported as 8 to 14 years (the range is 1 to 46 years) in the Antelope Lake watershed (Moody and Stephens 2002). In higher elevation red and white fir-dominated forests (up to approximately 6,400 feet in elevation), the average number of years between fires has been reported as 33.8 years (the range is 18 to 54 years) (Beatty and Taylor 2001). Prior to fire exclusion and intensive timber harvest of the early to mid-20th century, the relative frequent occurrence of fires generally contributed to open stands dominated by large-diameter fire-resistant trees with relatively low surface fuel loads with interspersed areas of young seral stands (Weatherspoon 1996). Prior to fire suppression policy in 1902, John Leiberg (1902) described the surface fuels in similar unharvested forests on the Plumas National Forest types as follows:

> *"There is no humus; the forest floor is bare, or at the most is covered with a layer of pine needles rarely exceeding 2 inches in depth, most commonly an inch or less."*

Given the spatial and temporal extent of past fires well documented in scientific literature (Taylor 2000; Moody and Stephens 2002; Skinner and Chang 1996), this type of surface fuel loading would have been much more common prior to fire exclusion than the ubiquitous high surface fuel loading found today. Overall, the historical vegetation structure, species composition, and surface fuels reflected, in part, past fire regimes as well as land management practices of both the Northern Maidu (Anderson 2005; Stewart 2003) and land uses of the thousands of settlers who moved to the Plumas County region after the gold rush (Young 2003).

The overall conditions in the analysis area are, in part, also described by the Fire Regime Condition Class (Table 20). The current conditions in the analysis area as described above are similar to those conditions which have led to high-severity fires within the vicinity of the analysis area, such as the Moonlight and Antelope Complex Fires of 2007, the Rich Fire of 2008, and the Stream Fire of 2001 (Duncan, personal communication 2010; Raley 2001). Of particular note, 71 percent of the NFS lands within the analysis area are in condition class 3 where "vegetation composition, structure, and fuels have a high departure from the natural fire regime and predispose the system to high risk of loss of key ecosystem components." (Hann and Strohm 2003).

Table 20. Fire Regime Condition Classes within the Keddie Ridge Analysis Area

Fire Regime Condition Class	Acres in the Analysis Area	Acres of NFS lands within the Analysis Area	Description
1	8,124 (8%)	4,132 (8%)	Vegetation composition, structure, and fuels are similar to those of the natural regime and do not predispose the system to risk of loss of key ecosystem components. Wildland fires are characteristic of the natural fire regime behavior, severity, and patterns. Disturbance agents, native species habitats, and hydrologic functions are within the natural range of variability.
2	24,898 (23%)	10,445 (19%)	Vegetation composition, structure, and fuels have moderate departure from the natural regime and predispose the system to risk of loss of key ecosystem components. Wildland fires are moderately uncharacteristic compared to the natural fire regime behaviors, severity, and patterns. Disturbance agents, native species habitats, and hydrologic functions are outside the natural range of variability.
3	61,342 (58%)	39,020 (71%)	Vegetation composition, structure, and fuels have high departure from the natural regime and predispose the system to high risk of loss of key ecosystem components. Wildland fires are highly uncharacteristic compared to the natural fire regime behaviors, severity, and patterns. Disturbance agents, native species habitats, and hydrologic functions are outside the natural range of variability.
9	11,537 (11%)	1,227 (2%)	Agriculture, Barren, Water, or Urban vegetation types.

Source: Hann and Strohm (2003)

Extensive development of residential homes in the Wildland Urban Interface (WUI) surrounding Indian Valley poses a continued risk of human-caused ignitions throughout dry summer months. The ignition risk puts residences on private lands in the analysis area at risk of wildfires that may occur on adjacent NFS lands; likewise, NFS lands are at risk from fires ignited on these private lands. In addition, large undeveloped areas of the forested wildlife habitat in the analysis area are at continued risk of high-severity fire and drought-related mortality. For more information regarding fuels within the project area, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A and B.

Forest Insect and Disease

Forest insects and disease currently occur in many stands in the analysis area and is well documented in the Forest Health Evaluation performed for the project (Cluck and Woodruff 2010). With the exception of white pine blister rust (*Cronartium ribicola*), an introduced disease, forest pathogens are endemic to forests as part of the natural disturbance regime. However, due to the interaction of past management activities (such as fire exclusion, unnaturally high stocking levels of shade-tolerant species, and drought) as well as climate change trends, populations of insects and disease may increase beyond endemic levels associated with forest health.

Bark beetles are the primary insects of concern found in the analysis area and are associated primarily with ponderosa and Jeffrey pines and true fir. Ponderosa and Jeffrey pines are susceptible to the western pine beetle, *Dendroctonus brevicomis,* and *Ips* species. The western pine beetle is the most aggressive and contributes to direct tree mortality, particularly in moisture-stressed trees within high-density stands where density driven competition is greatest. The primary prevention measure for this species is to maintain healthy vigorous trees in low stand densities where competition for water, light, and nutrients is minimized. The *Ips* species breed in activity slash and may grow beyond endemic levels in areas where logging slash is not properly treated. When populations build to sufficient numbers, the *Ips* beetle can attack mature trees.

The fir engraver bark beetle also occurs within the analysis area. The fir engraver bark beetle attacks true fir species and is associated with direct and indirect tree mortality, in combination with drought and disease occurrences in high-density stands (Ferrell 1996).

The primary pathogen of concern found in the analysis area is *Heterobasidion* root disease, caused by *Heterobasidion occidentale* and *Heterobasidion irregulare*. *Heterobasidion* root disease is known to occur throughout the forests of northern California and southern Oregon (Schmitt et al. 2000) and there are well-documented occurrences in both pine and fir species on the Plumas National Forest and neighboring Lassen National Forest (Kliejunas 1989; Woodruff 2006). The occurrence of *Heterobasidion* root disease has been confirmed in true fir and is suspected to occur in pine stands in the analysis area (Woodruff and Kliejunas 2005). There is the potential for new infection in any harvest area because spores can travel up to 100 miles (Goheen and Otrosina 1998).

While all western conifers are susceptible to this pathogen, ponderosa and Jeffrey pines and true fir tend to be most susceptible to adverse effects from the disease. This root disease is spread via spores infecting fresh wounds or stumps and from root-to-root contact (Sinclair et al. 1987). Stands with repeated entry in the analysis area have a higher incidence of the disease than un-entered stands. The effects of this disease range from reduced individual tree vigor, root and bole decay, windthrow, root mortality, and in the worst-case scenario, tree mortality.

Existing Conditions

Existing conditions of forested stands within the analysis area range depending on factors such as ownership, past management activities, and CWHR size class and density. In general, forested stands proposed for thinning treatments within the Keddie Ridge Project are primarily CWHR 4 and CWHR 5 size class stands. The average existing conditions and the range for each attribute are shown in Table 21.

Table 21. Existing Conditions of Forested Stands

Stand Attributes and Predicted Fire Behavior	CWHR 4 Stands				CWHR 5 Stands			
	Average	Range			Average	Range		
		Min	-	Max		Min	-	Max
Total Trees per acre	**479**	72	-	1475	**418**	135	-	741
Trees per acre 1-10 inches DBH	**395**	20	-	1300	**328**	56	-	621
Trees per acre10-20 inches DBH	**63**	0	-	167	**67**	15	-	107
Trees per acre 20-30 inches DBH	**14**	5	-	31	**16**	2	-	31
Trees per acre >30 inches DBH	**5**	0	-	16	**6**	1	-	17
Snags per acre >15 inches DBH	**3**	0	-	9	**3**	0	-	12
Snags per acre > 30 inches DBH	**0.3**	0	-	1.1	**0.4**	0	-	2.8
Basal area per acre (ft^2 per acre)	**190**	93	-	313	**208**	132	-	291
Relative Density (%)	**57**	29%	-	85%	**61%**	33%	-	80%
Quadratic Mean Diameter (inches)	**14.7**	10.5	-	22.6	**15.0**	11.6	-	22.6
Total Canopy Cover	**48**	31	-	73	**51**	35	-	66
Surface Fuel Load (tons per acre)	**26**	2	-	46	**33**	12	-	52
Predicted Total Flame Length (feet)	**21.6**	5.4	-	70.9	**20.4**	11.4	-	45.0
Predicted Probability of Torching	**80%**	30%	-	100%	**80%**	20%	-	100%
Predicted Fire Type	**Passive Crown Fire**	Surface Fire	-	Active Crown Fire	**Passive Crown Fire**	Passive Crown Fire	-	Passive Crown Fire
Predicted Percent Basal Area Mortality	**84%**	33%	-	93%	**85%**	67%	-	90%

These stands have high densities of trees, particularly in the 1-10 inch diameter class range, and some stands have high densities in the 10-20 inch range. These stands have high accumulations of ladder fuels and vertical continuity with canopy fuels, which in combination with the high surface fuel loads, are predicted to have large flame lengths, high amounts of tree torching, and primarily passive crown fire behavior resulting in large amounts of mortality under 90th percentile weather conditions. These high stand densities also increase stresses on larger more desirable retention trees due to increased inter-tree competition for finite site resources – particularly water during extended drought periods – which is interconnected to increases in bark beetle populations and subsequent tree mortality. For more information regarding forest health, existing conditions, and desired conditions, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A and B.

Air Quality

The analysis area is located in Plumas County, California. Nearby towns and communities are shown in Table 22. The entire project area is contained in the Northern Sierra Air Quality Management District (NSAQMD) within the Mountain Counties Air Basin.

Table 22. Communities Within the Vicinity of the Keddie Ridge Project Area

Community	Distance and Direction from Keddie Ridge Project Boundary
Greenville, Taylorsville, Crescent Mills, and Canyon Dam	Within the Keddie Ridge Project
Lake Almanor Basin communities (Chester, Prattville, Hamilton Branch)	~ 1 - 10 miles northwest
Susanville	~ 15 miles northeast
Genesee Valley	~ 1 - 3 miles east
Quincy	~ 7 miles south
Lassen National Park	~ 20 miles northwest

The air quality attainment status for ozone, carbon monoxide, sulfur dioxide, and other compounds is listed in Table 23. The attainment status was derived directly from the NSAQMD "2004 Annual Air Monitoring Report."

Table 23. Attainment Designations for Plumas County

Compound	National Attainment Status	State Attainment Status
Ozone (1 hour)	Attainment	Unclassified
Ozone (8 hour)	Attainment	Not applicable
Carbon monoxide	Attainment	Attainment
Nitrogen dioxide	Attainment	Attainment
Sulfur dioxide	Attainment	Attainment
PM_{10}	Unclassified	Nonattainment
$PM_{2.5}$	Unclassified	Nonattainment – only the Portola Valley is in nonattainment for the state $PM_{2.5}$ annual standard

Source: NSAQMD (2004 Annual Air Quality Report)

Currently, Plumas County is in nonattainment status for particulate matter (PM)10 (county wide) and $PM_{2.5}$ (Portola Valley only). The project area is approximately 26 miles northwest of Portola Valley at its closest point. According to the NSAQMD 2004 report, the major contributors to both PM_{10} and $PM_{2.5}$ levels include forestry management burns, residential woodstoves, residential open burning, vehicle traffic, and windblown dust. These problems can be relieved or made worse by local meteorology, winds, and temperature inversions. In addition, large areas in and adjacent to local communities can be heavily impacted by smoke for extensive summer periods (several weeks to months) due to wildfires such as in the 2007 Moonlight fire which occurred in the project area, and the 2008 Canyon Complex and Rich Fires, which occurred west of the project area.

The community of Quincy is subject to strong inversions and stagnant conditions in the wintertime. Those conditions, coupled with intensive residential wood burning, can result in very high episodic $PM_{2.5}$ levels. Levels of PM_{10} have been greatly decreased due to a reduction of non-EPA (Environmental Protection Agency) approved woodstoves in existing residences. The NSAQMD report noted four key points relating to current air quality within the NSAQMD:

1. The NSAQMD's state and federal nonattainment status for ozone is due to overwhelming air pollution transport from upwind urban areas, such as the Sacramento and Bay areas.
2. Improvements in air quality, with respect to ozone, will depend largely on the success of air quality programs in upwind areas.
3. Anticipated growth in local population will add to locally generated pollution levels. Therefore, local mitigations are needed to prevent further long-term air quality degradations. Otherwise, the local contribution may increase to the point where the transport excuse will become less viable, and more emphasis will then be placed on mandated local controls.
4. State and federal land managers anticipate a marked increase in prescribed burning within the next 5 years. This may have a tremendous impact on local PM_{10} and $PM_{2.5}$ levels, unless appropriate mitigations are employed.

Current sources of particulate matter from the analysis area include smoke from residential wood burning, large wildfires, smoke from underburning and pile burning, emissions and dust from standard and off-highway vehicles, dust and emissions from harvest activities occurring on private lands, smoke from campfires, and wind-generated dust from exposed soil surfaces. The amount and duration of these emissions vary by season, with most emissions from residential wood burning occurring from October to April, emissions from wildfires, timber harvest, and recreational activities occurring between May and September, and emissions from prescribed burning occurring from October through mid-November.

Environmental Consequences

Alternative B – No Action

Under alternative B, no actions would be implemented to address the areas of concern identified in the 2006 Keddie Ridge Project area Landscape Assessment (located in the project record) or objectives and desired conditions identified in the purpose and need sections in chapter 1.

Direct and Indirect Effects

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Existing stand conditions would persist and develop unaltered by active management, with the exception of continued fire suppression activities. Wildfire, drought, disease, and insect-related mortality and recruitment would continue to occur. Table 24 displays average stand attributes under the No action Alternative. *Under alternative B, there would be no reduction in trees per acre, basal area per acre or relative stand density*. *Under alternative B, stands would have, on average, 218 square feet of basal area and a relative stand density of 64 percent.* Stands would remain dense, particularly in the smaller diameter classes in terms of trees per acre and basal area.

Table 24. Average Stand Attributes under Alternative B.

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-Treatment Relative Stand Density	Post-Treatment QMD	Average Increase in Diameter
No Action	446	0%	100%	192	0%	57	14.9	0%

Oliver (1995) observed that northern California even-aged ponderosa pine stands whose densities exceeded Sartwell's (1971) basal area threshold of 150 square feet per acre were susceptible to *Dendroctonus* bark beetle attack. *Under alternative B, 74 percent of the stands are over this basal area threshold and pine species within these stands are at elevated risk of bark beetle mortality* (Fiddler et al. 1989; Oliver 1995). True fir species (white and red fir) may exist at higher stand densities. However, at high stand densities, root disease and drought increase the susceptibility of true fir species to mortality caused by the Scolytus fir-engraver beetle (Oliver et al. 1996; Guarin and Taylor 2005; Ferrell 1996; Macomber and Woodcock 1994).

These high tree densities would persist under alternative B, thereby reducing growth rates and tree vigor, and increasing risk of mortality due to inter-tree competition and increased incidence of insect activity (Ferrell 1996; Oliver et al. 1996; Oliver 1995). High densities of small trees may cause competition for soil moisture and nutrients, which could contribute to increased stress on larger, older trees (Dolph et al. 1995). *Under alternative B, 51 percent of the stands have relative stand densities that are at or greater than the "lower limit of the zone of imminent competition mortality"* (Drew and Flewelling 1977; Drew and Flewelling 1979; Smith et al. 1977). Within 10 years, approximately 69 percent of stands would have relative stand densities that exceed this threshold, within 20 years, approximately 77 percent of the stands would exceed this threshold, and within 30 years approximately 89 percent of the stands would exceed this threshold.

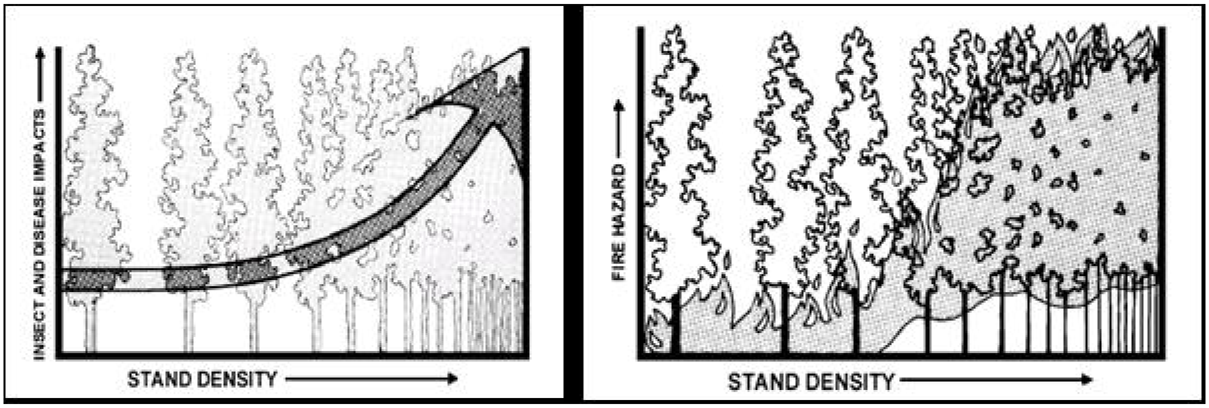

Figure 3. General Effects of Increasing Stand Density on (a) Insect and Disease Impacts, and (b) Fire Hazard as Described by Powell (1999)

The increasing stand density and consequent mortality due to inter-tree competition and increased incidence of insect activity may have a major adverse effect on forest health by decreasing tree vigor and growth; increasing susceptibility to insects, disease, and drought; and increasing susceptibility to intense fire behavior. The resulting stand structure would be characterized by a dense understory and midstory with interlocking crowns. These general trends, in relation to forest health and fire hazard, have been described by Powell (1999) and are shown in Figure 3.

Compositional Structure: Species Composition

Under alternative B there would be no change in species composition. The existing stand structure promotes a low light environment, which strongly influences species composition by favoring the regeneration, growth, and development of shade-tolerant species such as white fir, incense-cedar, and, to a lesser degree, Douglas fir. Overall, shade-tolerant species collectively account for 74 percent of trees and shade-intolerant tree species such as ponderosa pine, sugar pine, and black oak, account for only 26 percent, on average; however, this varies by stand, aspect, and elevation. Shade-tolerant species currently exist at high densities, particularly in trees less than 20 inches DBH while pine species (Ponderosa and sugar pines) generally occur as overstory trees (greater than 20 inches DBH); the number of pine regeneration in the understory is much lower relative to shade-tolerant species. These large dominant overstory pines are “legacy” trees that may be indicative of species composition in historical reference conditions. However, existing stand structure and high densities clearly favor the regeneration, growth, and development of shade-tolerant species. Currently, most mixed species stands in the analysis area are becoming more occupied by the shade-tolerant species mentioned above, and this trend would be expected to continue.

Such high densities of shade-tolerant species compete with shade-intolerant species for resources (nutrients, light, and water), increase shade in the understory, and discourage the regeneration of shade-intolerant pine species (Oliver et al. 1996). Consequently, over the longer temporal scale, a shift in species composition would be expected to occur, giving preference to regeneration of shade-tolerant species over shade-intolerant species (Minnich et al. 1995; Ansley and Battles 1998; Oliver et al. 1996;

McKelvey and Johnston 1992). Shade-tolerant species, white fir in particular, can be more susceptible to fire-related scorch mortality than shade-intolerant species such as ponderosa pine and Jeffrey pine (Skinner 2005; Stephens and Finney 2002; Mutch and Parsons 1998; Leiberg 1902). This susceptibility to mortality can lead to more trees being killed by wildfire-related scorch and damage to the cambium.

Landscape Structure and Heterogeneity: Tree Size and Canopy Cover

Currently, relative stand density in CWHR size classes 4 and 5 is at or just below the 60 percent threshold thereby increasing the risk for competition-related mortality. Over time, diameter growth and an increase in trees per acre due to ingrowth would contribute to an increase in stand density. In the absence of treatment or naturally occurring disturbance, such as fire, stand density would continue to increase beyond the threshold of 60 percent relative stand density into the “zone of imminent mortality”. This would have an adverse effect on tree growth and vigor and resistance to insects, disease, drought, fire behavior, and fire-related tree mortality.

The analysis area would continue to be dominated by closed-canopy mid-seral forested stands. These stands, best characterized by CWHR size class 4 and canopy density classes of Moderate (M) and Dense (D), contribute to landscape homogeneity due to its ubiquitous abundance and connected arrangement. Because such stand structure has increased vulnerability to high-severity fires, insect outbreaks, and landscape level drought-induced mortality, a homogenous (same species or structure) occurrence of these closed-canopy, mid-seral stages across the landscape is unstable and less resilient to the aforementioned forest disturbances (McKelvey and Johnston 1992).

Fuels and Potential Fire Behavior: Fuel Load and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Surface, ladder, and canopy fuels would remain untreated under the no action alternative, and, as a result, potential fire behavior including predicted flame length, probability of torching, fire type, and basal area mortality would remain unchanged. Table 25 displays the average fuel and potential fire behavior attributes under Alternative B.

Table 25. Average Fuel and Potential Fire Behavior Attributes under Alternative B

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
No Action	28	18	5	74%	22	Passive Crown Fire	85

Surface fuel loading would be 28 tons per acre, on average, and would range from 5 to 52 tons per acre, depending on individual stand conditions. Approximately 74 percent of stands would have surface fuel loading greater than 20 tons per acre. In addition, ladder fuels would not be removed so there would be continuity between surface, ladder, and crown fuels.

These conditions would result in flame lengths that would be 6 feet and greater under 90th percentile weather conditions. Over 91 percent of the stands would have flame lengths greater than 11 feet where crowning, spotting, and major fire runs are probable, and control efforts at the head of the fire are ineffective. These flame lengths, when combined with current stand structure, would result in a probability of torching of 74 percent, on average, and which would sustain passive crown fire activity. This potential fire behavior would result in high severity fire characterized by high basal area mortality. On average, stands would have 85 percent basal area mortality, and over 90 percent of the stands would have greater than two thirds of tree basal area mortality as a result of a fire under 90th percentile weather conditions. The predicted direct mortality from scorch and cambial damage does not account for post-fire mortality to fire-damaged trees due to insect and disease activity.

Continued high density, high fuel load, and high flame length conditions would (a) reduce the production rates for fire-line construction by hand crews and mechanical equipment, (b) compromise the safety of fire fighters and the public, and (c) decrease the effectiveness of aerially applied retardant. In addition, burning embers from burning trees and standing dead trees could be blown to unburned areas outside the main fire—this could potentially increase the fire size. These direct and indirect effects do not reflect the influence of the fire itself on local weather conditions (Colson 1956; Cramer 1954). At the landscape level, increased spotting tends to increase erratic fire behavior, resulting in increased fire size with higher tree mortality, (Schroeder and Buck 1970). The above factors would decrease the effectiveness of initial attack and extended fire suppression operations, leading to a greater potential for large, high-severity fires. Fires with this expected fire behavior and difficulty of suppression have already occurred within and adjacent to the analysis area. In 2007 the Moonlight Fire and the Antelope Complex Fires burned over 87,000 acres both within, adjacent, and within reasonable proximity to the analysis area, with over 62 percent of these acres burning under high severity (greater than 75 percent basal area mortality).

Under the no action alternative, fire management's ability to safely suppress and contain fires, both in initial attack and extended fire suppression operations, would not be improved and would continue to decline over time from current conditions due to continued stand densification and surface fuel buildup. Under 90th percentile weather conditions, over 91 percent of the stands would have flame lengths greater than 11 feet where crowning, spotting, and major fire runs are probable, and control efforts at the head of the fire are ineffective (Table 19). Under current surface fuel loadings and high stand densities, as represented by a Fuel Model TU-5 (Scott and Burgan 2005), the rates of fire-line construction are relatively slow for both hand crews and tractors when compared with the post-treatment desired conditions.

The above factors result in a major negative effect on the overall ability of fire managers to safely suppress and contain fires, leading to increased suppression intensity and cost. This increased suppression intensity can lead to a greater potential for resource damage during the fire and higher Burned Area Emergency Rehabilitation (BAER) costs after the fire is out. Implementation of alternative B would not establish a network of fuel treatments. Overall, the current predicted fire behavior for this alternative could lead to a greater potential for large, high-severity fires in forested areas, including the wildland urban interface, riparian habitat conservation areas, protected activity centers, and home range core areas in the analysis area during a wildfire under 90th percentile or worse weather conditions.

Direct and Indirect Effects: Air Quality

Under alternative B, treatments proposed under action alternatives would not occur; however, related uncontrollable emissions as described by the U.S. Environmental Protection Agency (2006) could occur from wildfires within the analysis area. This reality is supported by past fire events such as the Moonlight fire of 2007 and the Canyon Complex and Rich Fires of 2008 in which smoke impacted communities in and around the analysis area ranging temporally from a week to over a month of impacted air quality. Please refer to the Direct, Indirect, and Cumulative Effects discussion for Air Quality in the Comparison of Alternatives section.

Cumulative Effects Common to All Alternatives

The cumulative effects of past management practices, fire exclusion, and high-mortality fires (as detailed in appendix F) have largely shaped the forest that exists in the analysis area today. These factors have influenced vast areas of the Sierra Nevada mountain range and are well documented in the scientific literature as noted in Chapter 3. These past projects and events are reflected in the vegetation layer used to characterize the existing conditions (the baselines for analysis) in the analysis area. Changes in vegetation structure as a result of recent fires and past projects since the baseline data were collected have been incorporated into the Keddie Ridge Project’s existing conditions. Such activities have had major impacts at the stand level by converting mid to later seral forest to early seral structure; however, on the landscape scale, this has had a negligible impact due to the dispersed nature of these projects and their size relative to the analysis area.

On National Forest System lands and private lands, past harvest activities focused on selection and sanitation harvests resulting in overstory removal of dominant and codominant trees, and retention of midstory and understory trees. These harvest systems often used lop and scatter techniques for limb wood and tree tops. These practices resulted in promoting closed-canopy, high-density stands of small trees with relatively high fuel loads. Many of these stands continue to be conducive to high-mortality fire today.

Since the mid to late 1990’s, commercial and non-commercial thinning from below, with and without prescribed fire, has been the principal silvicultural treatment implemented on NFS and private lands in the analysis area. This silvicultural treatment has been used to establish several fuel treatments on NFS and private lands both within and adjacent to the analysis area (Green Flat and Lucky S Projects). These treated areas currently meet desired conditions in terms of potential fire behavior and tree mortality.

Herbicides have been used to control competing brush in conifer plantations and noxious weeds on private lands within the analysis area. A reduction of competing brush generally reduces stand-level flammability in plantations and increases rates of tree growth. These factors can shorten the length of time that planted trees remain vulnerable to scorch-related mortality. Past high-mortality fires in the Analysis area were typically replanted, and many of these areas are now dominated by young trees characteristic of CWHR size class 3.

Watershed and wildlife projects are not generally implemented at a scale or location to have an influence on landscape level vegetation or fire behavior and related tree mortality. In general, wildlife and watershed projects listed in “Appendix F: Past, Present, and Reasonably Foreseeable Future Actions,” have a negligible effect on stand development and landscape level fire behavior and related tree mortality. These small projects that improve riparian areas or improve wildlife habitat have a minor beneficial effect by enhancing vegetation diversity and decreasing fire behavior. In general, current road conditions and past road closures to benefit wildlife have had a negligible impact on the vegetation or fire management within the analysis area.

Other present and proposed future projects in the analysis area include wildlife, botanical, watershed, grazing, recreation, lands, minerals, and special use projects. These projects would not be expected to have a measurable effect on forest structure in the analysis area due to the localized and dispersed nature of scale and intensity of such projects. However, the primary minor adverse effect of these projects, particularly recreation activities, with respect to fire, is increased ignition sources from campfires, vehicles, and other intentional or unintentional ignitions from forest users during summer months.

Christmas tree cutting and firewood collection would likely have an adverse effect on regeneration and snag levels, particularly within localized areas around main roads. Christmas trees and firewood cutting have a negligible effect on stand- and landscape-level fire behavior. Levels of regeneration and snags outside of the main road corridors are unlikely to be affected due to recruitment in untreated areas and lack of access. Due to the seasonal and dispersed nature of these activities, there would be a negligible effect across the analysis area.

Present and proposed future fuels and vegetation management projects in the analysis area include the Moonlight Fire Recovery Project, Keddie Ridge Roadside salvage project, the proposed North Arm salvage project, the Maidu Stewardship Project, the Canyon Dam Fuel Reduction and Forest Health Project, the Empire Vegetation Management project, Plumas Fire Safe Council Projects, and Natural Resource Conservation Service Projects. Collectively, these projects represent less than 5 percent of the analysis area, and Forest Service projects represent less than 5 percent of National Forest System Lands.

Post-fire and insect salvage projects such as the Moonlight Recovery Project, the Keddie Ridge Roadside Salvage Project, and the North Arm Salvage remove dead trees and would result in the localized reduction of snags; however, snag retention guidelines would be incorporated into these projects. These effects would be highly localized and limited in scale to these project areas. Snags would be retained in the untreated portions of the Moonlight Fire which are large in extent, and snag recruitment would continue through insect related mortality. The North Arm Salvage project would remove dead and live trees to recover the value of dead trees and reduce stand densities to improve resistance to bark beetle related mortality of residual trees. This would result in creating an open canopy stand characterized by CWHR 4P.

Small hazardous fuels projects occurring on private lands such as the Plumas Fire Safe Council Projects, and Natural Resource Conservation Service Projects, include hazardous fuels reduction in the form of commercial and non-commercial mechanical thinning, hand thinning, piling and burning, or underburning. These activities would have a beneficial effect on the stand level by maintaining an open understory in these stands, thereby reducing high stand densities of small trees, ladder fuels, and fuel loading, fire risk, and potential fire behavior and effects. These projects are generally smaller in scale and highly dispersed through the analysis area. In addition, the treatments employed in these projects would not notably affect the overstory trees. Consequently these projects would result in a negligible impact on overall landscape structure because they are not likely to affect seral stage (as represented by CWHR size class) or overstory canopy (as represented by CWHR density class).

Larger hazardous fuels reduction projects occurring on National Forest System lands such as the Maidu Stewardship project, the Canyon Dam Fuel Reduction and Forest Health Project, and the Empire Vegetation Management Project also employ hazardous fuels reduction in the form of commercial and non-commercial mechanical thinning, hand thinning, piling and burning, or underburning. These activities would also have a beneficial effect on the stand level by maintaining an open understory in these stands, thereby reducing high stand densities of small trees, ladder fuels, and fuel loading, fire risk, and potential fire behavior and effects. These projects are typically larger in scale and have greater capacity to affect overstory tree density. The Maidu Stewardship project implements prescriptions which prohibit harvest of trees greater than 20 inches DBH and maintain canopy covers greater than 50 percent. These activities would not notably affect the overstory trees and would result in a negligible impact on overall landscape structure because they are not likely to affect seral stage (as represented by CWHR size class) or overstory canopy (as represented by CWHR density class).

The Canyon Dam Fuel Reduction Project and the Empire Vegetation Management project include prescriptions and treatments that would have a greater capacity to affect overstory trees and canopy cover. Within these projects, stands typed as CWHR 4 would allow for greater removal of canopy cover and trees less than 30 inches DBH. These activities would also have a beneficial effect on the stand level by creating open canopy stands, thereby reducing high stand densities of small trees, ladder fuels, and fuel loading, fire risk, and potential fire behavior and effects. This would result in the modification of mid-seral closed-canopy stands characterized by CWHR 4M and 4D to mid-seral open canopy stands characterized by CWHR 4P across 250 acres within the analysis area. Prescriptions for fuel treatments within CWHR 5 stands, however, would maintain greater than 40 percent canopy cover and would maintain both size class and closed-canopy conditions.

In addition, the Empire Vegetation Management project also includes mastication, area thinning and group selection treatments. Mastication treatments would primarily treat brush and small trees and would not affect CWHR size class or canopy cover. Area thinning treatments would primarily treat smaller trees and would maintain canopy cover greater than 50 percent, and consequently, would not affect CWHR size class or canopy cover. Group Selection treatments, however, would affect CWHR size class and canopy cover through removal of the majority of trees less than 30 inches DBH. This would result in converting approximately 58 acres of CWHR 4 and 15 acres of CWHR 5M into CWHR 1. Such small changes in CWHR size class would be very minor with relation to CWHR size and density distribution across NFS lands within the analysis area. The 5.5 percent increase in early seral conditions represented by CWHR size classes 1 and 2 are the result of group selection implemented under the Empire Vegetation Management project which fall into the analysis area. Figure 4 displays the cumulative effect of percent change in CWHR size class and density of other vegetation management projects within the analysis area under alternative B - the no action alternative.

	CWHR 1 & 2 (Seedlings & Saplings)	CWHR 3 (Pole-sized trees)	CWHR 4 (Small Trees)	CWHR 5 (Medium/Large Trees)
All	5.5%			
Dense		-0.5%	-2.5%	-4.8%
Moderate		-0.2%	-1.1%	3.2%
Open		0.3%	3.2%	0.0%
Sparse		0.0%	0.0%	0.0%

Figure 4. Percent Change in CWHR Size Class and Density of Other Vegetation Management Projects within the Analysis Area under Alternative B

Future DFPZ maintenance is not proposed in the analysis area at this time but is included in the cumulative effects analysis as a possible future event. The 2003 HFQLG Final Supplemental EIS and Record of Decision, in combination with the original HFQLG Act final EIS and Record of Decision, provide programmatic guidance for DFPZ construction and maintenance in the HFQLG pilot project area. The predicted maintenance treatments are described in "Appendix F: Past, Present, and Reasonably Foreseeable Future Actions." These maintenance activities could occur at least 10 years after implementation. The direct and indirect effect of such maintenance activities would maintain an open understory with reduced amounts of brush, tree regeneration, and naturally accumulating slash. These activities may reduce incidental numbers of snags, but may also induce snag recruitment through incidental tree mortality, particularly in prescribed fire treatments. The cumulative effect of DFPZ maintenance would be a reduction in tree regeneration and decreased recruitment of another age class of trees at the stand level; however, these treatments would maintain forest canopy and residual tree size. This, in turn, would retain stand structure and composition and would have a moderate beneficial effect on the long-term effectiveness of fuel treatments in terms of reducing fuel loading and potential fire behavior and effects.

Cumulative Effects of Alternative B

Alternative B would not meet the purpose and needs discussed in Chapter 1. With regards to Forest Vegetation, Fuels, Fire, and Air Quality, alternative B would not reduce hazardous fuel accumulations to improve forest health. Forest structure, species composition, landscape heterogeneity, fuel loadings, and potential fire behavior would remain unchanged. Overall, the existing forest and landscape structure and predicted fire behavior for this alternative could lead to a greater potential for large, high-severity fires in forested areas, including Wildland Urban Interface, riparian habitat conservation areas, protected activity centers, and home range core areas in the analysis area during a wildfire under 90th percentile or worse weather conditions.

The no action alternative would rely on density-dependent mortality, wildfires, and continued fire exclusion, to shape overall landscape structure. The maintenance of early seral stand structure would rely on areas of disturbance. The current landscape is dominated by mid-seral closed forests as represented by CWHR size classes 4M and 4D. No treatments would occur to enhance the development of mid-seral open-canopy forests. Stand densities would be expected to increase with time and would result in overall landscape homogeneity.

The maintenance of high stand densities across the landscape would result in the potential for adverse major impacts such as beetle outbreaks beyond endemic levels, widespread susceptibility to drought, and increased risk for high-mortality fire. These high stand densities and closed-canopy forests would favor a gradual shift in species composition toward shade-tolerant species, which would have an adverse effect on species diversity across the landscape. Such high-density stand structure is susceptible to forest health and fire hazard issues, and a homogeneous occurrence of these mid-seral closed-canopy forests across the landscape would be unstable (McKelvey and Johnston 1992). Alternative B would not provide for spatially variable, diverse stand structures across the landscape as described by Skinner (2005), Skinner and Chang (1996), Weatherspoon (1996), and the HFQLG final EIS (USDA 1999a), and it would not meet the desired conditions identified in the purpose and need sections in chapter 1 of this document.

Over the long-term, mortality occurring in high-density stands would continue to increase surface fuel load through deadfall of standing dead trees. This increase in mortality and related deadfall has been witnessed in the analysis area and other parts of the Sierra Nevada range as a result of region-wide drought in the late 1980s (Guarin and Taylor 2005). These increased surface fuels, combined with continuous ladder and canopy fuels, would continue to hinder suppression effectiveness, and would likely maintain stands susceptible to high-mortality fires such as the Moonlight and Antelope Complex Fires of 2007. The Moonlight and Antelope Complex Fires burned over 87,000 acres, with high severity (basal area mortality exceeding 75 percent) on 54,000 acres - the equivalent of over 84 square miles (USDA 2009c). Increased flame lengths during a wildfire could lead to high mortality in forested areas, including the Wildland Urban Interface, RHCAs, PACs, and HRCAs in the analysis area. In turn, this may result in large-scale adverse impacts to air quality and continued high fire suppression and rehabilitation costs for the indefinite future in the analysis area.

The no action alternative would not improve firefighter and public safety, which could lead to potential future injuries or fatalities during wildfire events. The no action alternative would also not reduce potential tree mortality or protect rare species and associated habitat from the major adverse effects of severe wildfire (Stephens and Moghaddas 2005a; Agee 2002). Reasonably foreseeable fuel treatment projects (appendix F) would be implemented at the stand level although they would mostly remain geographically separated. Alternative B would not provide continuity between existing and future fuel treatments, thereby decreasing their overall effectiveness at the landscape level. At the landscape level, the current Fire Regime Condition Class would not be modified over the short-term. Modifications over the long-term would be primarily caused by high-mortality fires and drought and insect-related mortality, none of which would trend the landscape-level Fire Regime Condition Class towards Condition Class I (refer to the "Glossary" for a definition of Fire Regime Condition Class). The no action alternative would allow stands to continue to develop under the influence of the legacy of past management practices and fire suppression (Skinner 2005; Agee 2002). Overall, the no action alternative would trend conditions for fire behavior and predicted mortality away from the desired conditions described in chapter 1.

Effects Common to All Action Alternatives (Alternatives A, C, D, and E)

Design Criteria

Chapters 1 and 2 provide detailed information about the Design Criteria used for each alternative**.** The harvest systems were determined by evaluating topography, slope, and access for each unit. Ground-based mechanical and skyline harvest systems are proposed (chapter 2). All mechanical harvest operations would adhere to the standards and guidelines set forth in the timber sale administration handbook (Forest Service Handbook [FSH] 2409.15, including Region 5 supplements) and the best management practices as delineated in the "Water Quality Management for Forest System Lands in California: Best Management Practices" (USDA 2000c).

Direct and Indirect Effects of Timber Harvest

In general, the direct and indirect effects described below would be common to all action alternatives that propose mechanical harvesting as a treatment regardless of silvicultural prescription. The effects of the specific silvicultural prescriptions proposed under the action alternatives are described in the subsequent subsections. However, all treatments involving mechanical harvesting using ground-based and skyline logging systems would share similar effects that include the potential for damage to residual trees; incidental removal of snags and trees greater than 30 inches in diameter; the construction of skid trails, landings, and temporary roads to facilitate logging operations; and the creation of activity-generated slash. Implementation of mechanical treatments is expected to maintain near-current total volume of snags and woody debris greater than 10 inches in diameter (Stephens and Moghaddas 2005c).

Throughout all treatments, regardless of silvicultural prescription, trees greater than 30 inches in diameter would be retained in accordance with the 2004 Record of Decision on the SNFPA Final Supplemental EIS (table 2)(USDA 2004b). In general, trees in the 20- to 30-inch diameter classes and the greater than 30-inch diameter classes would be the favored tree sizes to retain. These larger trees have favorable attributes in terms of fire resistance, desired stand structure, and wildlife habitat. In pine-dominated mixed conifer forest types, shade-tolerant species (such as white fir, incense-cedar, and to a lesser degree, Douglas-fir) would be targeted for removal, particularly in the smaller diameter classes. Shade-intolerant species such as Jeffery pine, ponderosa pine, and sugar pine would be retained. In true fir-dominated forest types, species preference would be weighted towards maintaining naturally occurring shade-intolerant species such as Jeffery pine; however, species composition would be maintained at levels appropriate for that ecological forest type.

Damage to residual trees may occur during harvesting operations including damage to stems, bark scraping, wrenched stems, broken branches, broken tops, and crushed foliage (McIver et al. 2003). These effects are typical in logging operations, but care would be taken to minimize the potential for damage to residual trees. The Forest Service would inspect timber sales during harvesting to ensure that damage to residual trees is within reasonable tolerances.

In accordance with the 2004 Record of Decision on the SNFPA Final Supplemental EIS (table 2, page 69)(USDA 2004b), four to six snags per acre that are 15 inches in diameter or greater would be retained within treatment units dependent on forest type and treatment (refer to the “Design Criteria” section in chapter 2). Incidental removal of snags may occur for operability and safety; however, guidelines set forth in the Pacific Southwest Region and Plumas National Forest Product Theft Prevention and Investigation Plan would be used to ensure that operability, safety, and minimum snag densities would be met. The snags to be retained would receive preference in locations where operability and safety are not anticipated to be issues. Snags within falling distances of roads, landings, and heavily used public areas would receive preference for removal where desired levels of large down woody debris have been met. Where minimum snag densities do not currently exist, marking guidelines would provide for the retention of large live trees with wildlife habitat characteristics (such as multiple or broken tops, crooks, and/or bole cavities) to serve as future snag recruitment. For additional information regarding snag retention and recruitment, please see the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C.

Existing skid trails, landings, and temporary roads would be used, when available, to facilitate the harvesting and removal of forest products (biomass and sawlogs). Skid trails, landings, and temporary roads could be constructed under all action alternatives to facilitate the removal of forest products when existing infrastructure does not exist. Under all action alternatives, no more than 6.8 miles of temporary road would be constructed, and any temporary roads constructed would be decommissioned after use. Construction of skid trails, landings, and temporary roads would require incidental removal of trees beyond those described for silvicultural purposes. This may include incidental removal of trees greater than 30 inches in diameter for operability. However, the location and size of skid trails, landings, and temporary roads, and the trees harvested for the construction of such facilities must be approved and agreed upon by the Forest Service. The removal of trees for operability would be incidental and minimized, and therefore, would have negligible effects on stand structure.

All action alternatives propose to use whole-tree yarding to treat slash generated by harvest activity. The removal of limbs and tops by such methods would greatly reduce activity-generated surface fuels (Agee and Skinner 2005). Some of the skyline units would not include whole-tree yarding due to feasibility constraints, but would treat biomass and residual slash through piling and burning of this material. The majority of trees would be removed using whole-tree yarding, which would effectively reduce the potential for activity-generated fuel accumulation. Slash would be lopped and scattered to minimize fuel bed depth, continuity, and arrangement if whole-tree yarding is not feasible (such as when mechanical yarding of an individual large tree would result in excessive damage to a residual stand). The net effect may result in incidental activity-generated fuel accumulations. Underburning would be used, as determined by post-treatment evaluations, to reduce activity-generated and existing fuels.

Alternative A – Proposed Action

Treatments and silvicultural prescriptions under alternative A were designed using the conceptual framework present in recent scientific literature regarding ecosystem management strategies for the Sierran Mixed-Conifer Forests (North et al. 2009). These concepts include: 1)emphasizing the importance and long-term enhancement of shade-intolerant species such as ponderosa pine, Jeffrey pine, sugar pine, and black oak, 2) reducing surface fuels, ladder fuels, and canopy fuels as appropriate to approximate an active-fire adapted stand structure, 3) reducing stand densities as appropriate to accelerate the development of large leave trees and improve stand resilience to agents of change such as fire, drought, insect and disease occurrences, and changing climate, 4) maintaining defect trees and intermediate-sized and large sized trees, which provide legacy structure that serves as important attributes of wildlife habitat, and 5) promoting heterogeneity at multiple scales (both within-stand and landscape level variability) to enhance structural diversity at the stand level, while creating landscape level diversity of seral stages and open-canopy stands which is more characteristic of an active-fire adapted forest.

Treatments and silvicultural prescriptions would be compliant with and would primarily implement the standards and guidelines for the Herger-Feinstein Quincy Library Group pilot project area as described in Table 2 of the 2004 Sierra Nevada Forest Plan Amendment ROD (USDA 2004b). Under alternative A, acres of group selection would be less than the amount allowed under full implementation of the HFQLG Pilot project, and group selection and mechanical thinning treatments would generally implement lower upper diameter limits for retention of intermediate and large-sized desirable shade-intolerant species. Table 26 displays the treatments, prescriptions, and corresponding acres that would be implemented under alternative A.

Table 26. Treatments, Prescriptions, and Corresponding Acres Proposed under Alternative A.

Type	Treatment	Prescription	Acres
DFPZ	Hand Thinning	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn.	1,026
	Mastication	Rx 6: Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH.	357
	Mechanical Thinning	Rx 2: Thin to 30 – 40 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; except in CWHR 5M/5D, thin to 40-50 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	824
		Rx 3: Thin to 30 – 40 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; except in CWHR 4M/4D, thin to 40 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; in CWHR 5M/5D thin to 40-50 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	255
		Rx 4: Thin to 30 to 40 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; except in CWHR 5M/5D, thin to 40-50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; in RHCAs thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	870
		Rx 5: Thin to 40-50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH and underburn.	180
		Rx 8: Thin to 30 – 50 percent canopy cover, generally retain live trees greater than or equal to 12 inches DBH, and underburn.	206
	Prescribed Fire	Rx 7: Low to moderate intensity prescribed underburn. Aproximately 73 acres within a spotted owl habitat area (SOHA) would be underburned at low intensity.	1,456
Area Thinning	Hand Thinning	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn.	231
	Mechanical Thinning	Rx 3: Thin to 30 – 40 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; except in CWHR 4M/4D, thin to 40 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; in CWHR 5M/5D thin to 40-50 percent canopy cover, generally retain live trees greater than or equal to 24 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	262
Group Selection		Harvest trees less than 30 inches DBH . Consider retaining healthy vigorous undamaged trees of desired shade intolerant species greater than 20 inches for seed tree and forest structure purposes, where appropriate.	284

Direct and Indirect Effects: Hand Thinning Treatments

The effects of pile burning treatments would be highly localized and dispersed. These effects would include scorch and subsequent mortality of individual trees; however, this would be a negligible effect due to the relative scale and dispersion associated with the nature of these treatments. These treatments would reduce understory vegetation and would result in incidental mortality in the midstory but would not be expected to change CWHR size class or density class. Hand thinning treatments are analyzed for hand thinning, piling, and burning, as well as follow-up underburning where conditions permit. Table 27 displays the average post-treatment stand attributes for hand thinning treatments that would be implemented under alternative A.

Table 27. Average Post-Treatment Stand Attributes for Hand Thinning Treatments under Alternative A

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
Rx1	179	-46%	100%	160	-9%	42	16.9	7.3%

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Hand thinning treatments would reduce stand density through hand thinning, piling, and burning trees less than 8 inches in DBH. These treatments would reduce trees per acre by 19 to 62 percent while retaining all trees greater than 8 inches DBH.

Hand thinning treatments would also reduce basal area per acre by 9 percent to 160 square feet of basal area, on average. The reduction of basal area would be limited to trees less than 8 inches DBH. Approximately 53 percent of stands would be thinned to less than 150 square feet; in the remaining 47 percent of the stands hand thinning alone is not sufficient to reduce basal area below the 150 square foot basal area threshold.

Hand thinning treatments would reduce relative stand densities to desirable level post-treatment. Fifty-three percent of stands proposed for hand thinning would have relative stand densities of 40 percent or lower. Approximately 11 to 16 percent of these stands would have higher relative stand densities than desired 20 to 30 years in the future and would need to be evaluated for re-treatment.

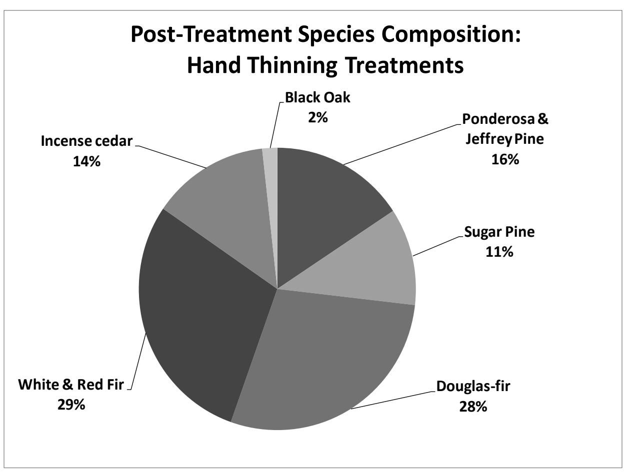

Figure 5. Average Post-Treatment Species Composition of Hand Thinnning Treatments under Alternative A

Species Composition

On average, hand thinning treatments could increase shade-intolerant species composition by 1 percent; however, depending on individual stand conditions, this increase could be as much as 4 percent. Hand thinning treatments would not have a notable effect on overall stand species composition primarily because these treatments limit tree removal to trees less than 8 inches DBH, and consequently, have little effect on basal area distribution by species.

Landscape Structure and Heterogeneity: Stand Size Class and Density

Hand thinning treatments would not enhance development into the next size class or notably affect stand canopy cover. Hand thinning treatments would increase the quadratic mean diameter of treated stands by 7 percent on average and would also decrease stand canopy cover; however, these reductions be negligible as the vast majority of the trees that would be removed would be from the understory.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Hand thinning, piling, and burning treatments would reduce excess surface fuels through piling and burning of existing dead and down material and ladder fuels through hand thinning, piling, and burning trees less than 8 inches DBH. In addition, follow-up underburning would further reduce surface fuel loading. Table 28 displays the average post-treatment fuel and potential fire behavior attributes of hand thinning treatments under alternative A,

Table 28. Average Post-Treatment Fuel and Potential Fire Behavior Attributes of Hand Thinning Treatments under Alternative A

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
Rx1	12	< 1	9	Incidental	25.0	Surface Fire	13

Hand thinning treatments would result in a reduction in predicted flame lengths, probabilities of torching, and basal area mortality by raising the canopy base height and reducing surface fuel loads. The resulting predicted fire type would be surface fire. The longevity of these treatment effects would last between 10-20 years until flame lengths increase above 4 feet where direct attack with handline is not feasible. Based on observations on the 2001 Stream Fire (Beckman 2001), the 2006 Boulder Fire, the 2007 Antelope Complex Fire (Fites et al. 2007), and recent scientific literature (Fule et al. 2006, Safford et al. 2009), lighter intensity, hand thinning treatments may not be as effective as mechanical treatments in modifying ladder and crown fuels and resulting fire behavior or tree mortality, dependent on individual stand conditions. Consequently, hand thinning treatments are prescribed for specific stand conditions where removal of smaller diameter material alone may be effective.

Direct and Indirect Effects: Mechanical Thinning Treatments

Mechanical treatments would be employed in both DFPZ and Area Thinning treatments. These treatments are designed to meet the purpose and need for reducing hazardous fuels, improving forest health, and protecting and enhancing habitat for sensitive species. Only a third of mechanical thinning treatments would occur in later seral forested stands best characterized by CWHR size class 5.

Silvicultural prescriptions under alternative A would implement a diverse range of canopy covers and species/objective specific diameter limits depending on CWHR type and maintenance of values discussed above. For example, prescriptions under alternative A would reduce canopy cover to lower limits within mid-seral CWHR 4M and 4D stands to accelerate growth of residual trees into later-seral open canopy stands characterized by CWHR 5; however, treatments in CWHR 5 stands and riparian habitat conservation areas would maintain more closed-canopy conditions as well as more intermediate and large-sized trees to retain later seral structure. These treatments, when combined with group selection and other treatments would enhance both within-stand and landscape level heterogeneity by creating horizontal diversity including canopy gaps and open canopy stand conditions favorable for the establishment and development of shade-intolerant species as well as clumps of closed-canopy stands with more vertical structural diversity.

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Mechanical treatments would reduce stand density through thinning and removal of conifers up to 29.9 inches DBH. Table 29 displays the average post-treatment stand attributes for mechanical thinning treatments that would be implemented under alternative A by prescription. On average by prescription, these treatments would reduce trees per acre by 36 to 68 percent, however, dependent on individual stand conditions this could range from 17 to 91 percent. The vast majority of the trees removed would be less than 20 inches DBH. *On average, 97 percent of trees greater than 20 inches DBH would be retained. Depending on the individual stand conditions, a minimum of 73 to 100 percent of the trees greater than 20 inches DBH would be retained.*

Table 29. Average Post-Treatment Stand Attributes for Mechanical Thinning Treatments that would be Implemented under Alternative A by Prescription

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
Rx2	127	-68%	73%	137	-34%	35	18.8	30%
Rx3	169	-58%	87%	155	-24%	38	18.0	24%
Rx4	226	-49%	94%	144	-22%	40	16.8	19%
Rx5	210	-36%	100%	175	-8%	44	16.5	8%
Rx8	214	-62%	100%	124	-18%	38	14.2	15%
Average	177	-57%	73%	147	-25%	38	17.7	23%

Basal area per acre would be reduced by 25 percent on average for all mechanical treatments. By prescription, basal area reduction would average between 8 and 34 percent; however, dependent on individual stand conditions and CWHR type, basal area reduction could range from 5 to 63 percent. *Basal area per acre would be reduced below the 150 square feet per acre threshold in 70 percent of the treated stands.*

In addition, relative stand densities would be reduced to desirable levels post-treatment. *Two-third of the stands would have relative stand densities within desired conditions immediately post-treatment.*

Within 20 to 30 years after treatment, only 7 percent of stands would have relative stand densities that would exceed the 60 percent threshold and would need to be evaluated for re-treatment.

Species Composition

Mechanical thinning treatments would employ species preference guidelines to enhance species composition of the residual stand. Prescriptions that generally retain trees greater than 24 inches DBH would allow for the removal of undesirable trees such as, a shade-tolerant white fir, up to 29.9 inches DBH if it is competing with a desired tree such as shade-intolerant ponderosa pine or a legacy tree greater than 30 inches DBH or within proximity of a group selection unit where shade-intolerant regeneration would be emphasized. On average, species stand composition of shade-intolerant species would increase by 5 percent; however, depending on individual stand conditions, this increase could be as much as 30 percent or in the case of 14 percent of the stands, result in no change in shade-intolerant species composition.

Landscape Structure and Heterogeneity: Stand Size Class and Density

The average increase in stand quadratic mean diameter would be 23 percent under mechanical thinning prescriptions in alternative A. This increase in stand quadratic mean diameter would enhance the development of CWHR 4 stands into CWHR 5 stands. Within 30 years of growth, approximately 39 percent of stands would have stand quadratic mean diameter of 24 inches or greater which is the threshold used to classify CWHR size class 5.

Canopy cover would be reduced through mechanical treatments; however, alternative A provides a range of prescriptions which would create a diverse range in canopy covers. Canopy cover in CWHR 4 stands could be reduced down to 30 percent canopy cover while canopy cover in CWHR 5 stands would be maintained above 40 percent, at a minimum, and canopy cover would be maintained at 50 percent with RHCAs.

The prescriptions for mechanical thinning are designed to create both horizontal and vertical structural heterogeneity best characterized by an open canopy stand with gaps of low densities/canopy cover and clumps of high density/canopy covers. CWHR 4 stands would receive heavier thinning (removal of more trees and canopy cover) to create open canopy stands and enhance diameter growth of residual trees into CWHR 5. CWHR 5 stands would receive lighter thinning (less removal of trees and canopy cover) to maintain closed-canopy stand conditions of later seral stands while reducing ladder fuels and stand density to reduce negative impacts of future fires, drought, and insect and disease occurrences.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Mechanical thinning treatments would reduce ladder and canopy fuels, whole-tree yarding would minimize the addition of activity fuels, and follow-up prescribed fire treatments would reduce surface fuels. In combination, these treatments would reduce fuel loadings and predicted flame length, probability of torching, fire type, and basal area mortality of potential future fires. Table 30 displays the average post-treatment fuels and potential fire behavior attributes for mechanical thinning treatments under alternative A by prescription.

Table 30. Average Post-Treatment Fuels and Potential Fire Behavior Attributes for Mechanical Thinning Treatments under Alternative A by Prescription

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
Rx2	14	< 1	33	Incidental	41	Surface Fire	10
Rx3	12	< 1	18	Incidental	25	Surface Fire	12
Rx4	11	< 1	20	Incidental	26	Surface Fire	13
Rx5	9	< 1	14	Incidental	22	Surface Fire	12
Rx8	11	< 1	21	Incidental	31	Surface Fire	15
Average	12	< 1	22	Incidental	30	Surface Fire	12

Fuel loading would be reduced to 12 tons per acre, on average, and would range between 3 and 25 tons per acre. Mechanical treatments alone would compact and crush existing surface fuels and greatly reduce ladder fuels to reduce potential fire behavior prior to prescribed fire treatments. However, the prescribed fire treatments would reduce existing surface fuels even further and allow for the re-introduction of fire into the ecosystem.

Flame lengths would be notably reduced – to less than 1 foot on average, well below the 4 foot threshold which would allow for direct attack utilizing hand crews. The probability of torching would also be greatly reduced – to incidental amounts which would substantially reduce the likelihood of passive crown fire initiation. Potential for torching would be restricted to islands of untreated areas such as control areas, small pitches of steep, untreatable ground, and clumps retained with high canopy cover and vertical structure of retained understory trees.

Potential fire type would be reduced from high severity passive crown fire as sustained under existing conditions to a low severity surface fire due to the treatment's reduction of surface, ladder, and crown fuels. Consequently, potential basal area mortality would also be reduced to 12 percent on average, and would range from 4 to 20 percent. All of the treated stands would result in low severity fire.

Direct and Indirect Effects: Mastication Treatments

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Mastication treatments would occur in plantations and pole sized stands and would re-arrange shrub fuels and conifer tree ladder fuels less than 10 inches in diameter. Post-treatment residual conifer tree spacing would range from 25 to 30 feet, on average, resulting in approximately 50 to 110 trees per acre. Trees per acre and basal area per acre would be reduced as well as relative stand density.

Species Composition

Mastication treatments would employ species preferences to retain species native to the forest stand ecological type. Desired shade-intolerant species such as black oak, ponderosa and Jeffrey pine, rust-resistant sugar pine, and Douglas-fir would typically receive preference for retention while allowing for a diverse mix of species occupying the site. While mastication treatments are limited in their capacity to treat trees less than 10 inches DBH, the treatment's capacity to affect species composition change is greater than hand thinning or 12 inch mechanical thinning because mastication would occur in stands where the vast majority of trees are less than 10 inches DBH.

Landscape Structure and Heterogeneity: Stand Size Class and Density

Mastication treatments would create open canopy stands within plantations and naturally occurring pole sized (less than 11 inches DBH) stands. These treatments would enhance the development of CWHR 2 and 3 sized stands into CWHR 4 sized stands with Open (P) and Sparse (S) canopy cover (less than 39 percent canopy cover).

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Mastication treatments would increase and compact surface fuels by modifying aerial arrangements of shrubs and ladder fuels (small trees less than 10 inches DBH) into a compact surface fuel bed. While these treatments actually increase surface fuel loads, the treatments also reduce vertical continuity of fuels and modify potential fire behavior in terms of flame length and rate of spread.

The reduction of the vertical continuity of fuels would reduce the probability of torching and the initiation of passive crown fire. This would result in surface fire behavior; however, potential fires would likely have higher fireline intensities which would influence direct attack and fire suppression strategy. Basal area mortality would likely remain high where fire occurs as stems of the small trees are exposed to high levels of heat from the increased fuel bed and residence time of burning fire (Fites et al. 2007).

Direct and Indirect Effects: Prescribed Fire Treatments

The effects of prescribed fire treatments in all action alternatives are expected to be the same. Underburning is nonselective, and it may kill some dominant and codominant trees that may have otherwise been retained in mechanical treatments. Implementation of prescribed burning treatments would have a negligible to minor effect on species composition in underburn units. According to the HFQLG Final Supplemental EIS (page 19), overall, the overstory canopy would not be affected by underburning, although torching of individual or small groups of trees would occur on up to 10 percent of the burn area where high surface fuel concentrations and ladder fuels can occur together. Torching may result in gaps in the canopy typically less than 0.5 acre in size. Localized torching from underburning would occur, thereby creating small openings in the overstory where shade-intolerant species may become established and grow, depending on size.

Implementation of prescribed burning is expected to reduce surface fuel loading including existing rotten woody debris, but overall would strive to maintain the current total volume of snags and woody debris greater than 10 inches in diameter (Stephens and Moghaddas 2005c). Prescribed burn-only treatments are expected to result in standing dead snags (Stephens and Moghaddas 2005c) that will likely fall to the ground within 5 to 10 years, thereby maintaining surface woody debris. Prescribed fire-only treatments may need to be treated sooner than mechanical fuel treatments (Fernandes and Botelho 2003).

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Prescribed fire treatments would reduce trees per acre, basal area per acre and relative stand density. Prescribed fire treatments would reduce trees per acre by causing fire-induced mortality primarily in the 1 to 10 inch diameter classes and some mortality in the 10 to 20 inch diameter classes. Mortality in the larger diameter classes may occur as the result of torching and/or delayed conifer mortality as a result of fire-damage and subsequent bark beetle attack.

Species Composition

Prescribed fire treatments would not notably affect species composition. However, prescribed fire treatments are the first step in the process of re-introducing fire into landscapes that have not burned for decades. Multiple entries of prescribed or natural fire may favor fire adapted shade-intolerant species over decades if not a century.

Landscape Structure and Heterogeneity: Stand Size Class and Density

Prescribed fire treatments would not notably affect stand size class and density. Prescribed fire treatments would incur mortality of the smaller diameter trees, primarily those less than 10 inches in diameter with some incidental mortality of larger trees due to torching or post-fire delayed conifer mortality. Prescribed fire treatments would reduce vertical structure by preferentially consuming understory and mid story vegetation. Canopy cover density could be reduced by isolated torching events, however, most tree mortality resulting from prescribed fire treatments would occur in the understory which would not notably affect the overstory canopy cover. Multiple entries of prescribed or natural fire may begin to enhance forest structure and heterogeneity over decades if not a century.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Prescribed fire treatments would reduce surface fuel loading and incur mortality of ladder fuels. Prescribed fire treatments would modify fire behavior by consuming surface fuel and would result in lower predicted flame lengths and probability of torching, similar to a low load compact conifer timber litter fuel model (as described by TL-1 in Scott and Burgan 2005), which has flame lengths well below 4 feet. This, in turn, would modify potential fire type which would be best characterized by surface fire resulting in low basal area mortality.

Over the period of decades, mortality from prescribed fire treatments would fall to the ground as fuel loading recruitment. This would result in increasing fuel loads, probability of torching, and fire type as well as basal area mortality, and result in the need for maintenance re-treatment.

Direct and Indirect Effects: Group Selection Treatments

Alternatives A and E would implement group selection harvest as directed by the Herger-Feinstein Quincy Library Group Forest Recovery Act (HFQLG Act)(USFS 1999a, b) to “test the effectiveness of an uneven-aged silvicultural system in achieving an uneven-aged, multistory, fire-resilient forest; provide an adequate timber supply that contributes to the economic stability of rural communities; and improve and maintain ecological health of the forest.”

The group selection method would create openings in the canopy to mimic gaps caused by natural agents, thereby emulating regeneration of a multicohort (multiple age classes) system across the landscape (York et al. 2003; Helms and Tappeiner 1996). Bonnicksen and Stone (1981, 1982) describe the southern mixed conifer forest of the Sierra Nevada as consisting of “mosaic aggregations in a space-time system.” The aggregations (collections) of cohorts (groups of individuals commonly consisting of trees of similar age [Helms 1998]) created using the group selection system may be used to increase diversity in forest structure on the landscape scale (McDonald and Abbot 1994), as well as promote the regeneration, growth, and development of shade-intolerant species (Leak and Filip 1977).

The ability of group selection to promote the regeneration, growth, and development of shade-intolerant conifer species is largely dependent on the size of the opening (York et al. 2004; McDonald and Reynolds 1999). “Seedlings of very shade-intolerant species such as ponderosa pine require a minimum of 30 percent full sunlight to survive in the understory” (Oliver and Larson 1996). The amount of sunlight reaching the group is a function of group size relative to the surrounding codominant and dominant tree height on the edge of the group. Consequently, those trees in the center of the group selection receive the most amounts of light and water, while those trees near the edge receive partial shade and must compete with surrounding codominant trees for water resources (York et al. 2003). A range of group selection sizes would be used to most appropriately “fit” the site requirements to encourage the regeneration, growth, and development of shade-intolerant species. Group selection openings would range in size from 0.5 acre to 2 acres, averaging 1.5 acres in size.

The group selection silvicultural system is designed to create a regulated, uneven-aged stand over time comprised of a balanced distribution of different age classes. The combination of DFPZ, area thinning and group selection harvest methods would strive to emulate gap dynamics of an uneven-age forest system. This system focuses on maintaining forest structure while providing openings that encourage regeneration, growth, and development of shade-intolerant species, and it may be effective in enhancing structural and compositional diversity, which contributes to the ecological health of the forest.

Group selection treatments are designed to promote the establishment, growth, and development of a new age class – or cohort – of shade-intolerant tree species such as ponderosa pine, Jeffrey pine, and rust-resistant sugar pine. Black oak and all trees greater than or equal to 30 inches DBH would be retained. Under alternative A, over 85 percent of group selection treatments would be occur in CWHR 4 stands to convert mid-seral closed-canopy stands dominated by less desirable shade-tolerant species into early seral open canopy openings where establishment, growth, and development of desirable shade-intolerant species is more favorable. Those group selection treatments that would occur in CWHR 5 stands would be strategically placed in areas dominated by uniformly sized, smaller shade-tolerant species.

Site preparation and regeneration needs would be evaluated after harvest. Those Group Selection Units requiring natural and activity slash treatment would undergo “site preparation” via machine piling, brush raking, hand piling, and/or underburning to clear any activity slash and debris that would prevent site regeneration.

Both artificial and natural regeneration would be used to reforest group selection units. A combination of natural and artificial would be used to achieve desired stocking levels, with an emphasis on regenerating shade-intolerant species. Those units requiring artificial regeneration would be planted with a mix of species native to the ecological forest type. Species to be planted would include Jeffrey pine, ponderosa pine, rust-resistant sugar pine, Douglas-fir, and incense cedar. Natural regeneration would be used for incense cedar, white fir, and red fir species. This regeneration method would have a major beneficial effect on enhancing desired species composition on both the stand and landscape scales.

After establishment of regeneration, release treatments (manual grubbing and/or pre-commercial thinning) would be used to reduce competing vegetation to favor the growth and development of desired species. Without release treatments, shrub and naturally regenerated tree species would likely compete with desired species and slow the growth and development into subsequent seral stages. Over time, these treatments would contribute to the development from seral stages CWHR SMC 1 and 2 to CWHR 3, represented by a quadratic mean diameter greater than 6 inches.

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Group Selection treatments would reduce trees per acre by greater than 90 percent, on average, and would reduce basal area per acre by 74 percent on average. Relative stand density would also be greatly reduced to levels far less than 25 percent; however, this would be favorable for promoting the establishment, growth, and development of shade-intolerant tree species.

Species Composition

Species composition of shade-intolerant tree species would be enhanced through two mechanisms: 1) the preferential retention of healthy vigorous pine and black oak species as seed trees, if available on site, and 2) planting a mix of tree species native to the ecological type while emphasizing the shade-intolerant species in that forest type. These two mechanisms would enhance the establishment of shade-intolerant species. Group selection treatments would increase relative proportions of desirable shade-intolerant species such as ponderosa pine, sugar pine, and black oak, (accounting for more 50 percent) and would decrease relative proportions of less desirable shade-tolerant species such as white fir (Figure 6).

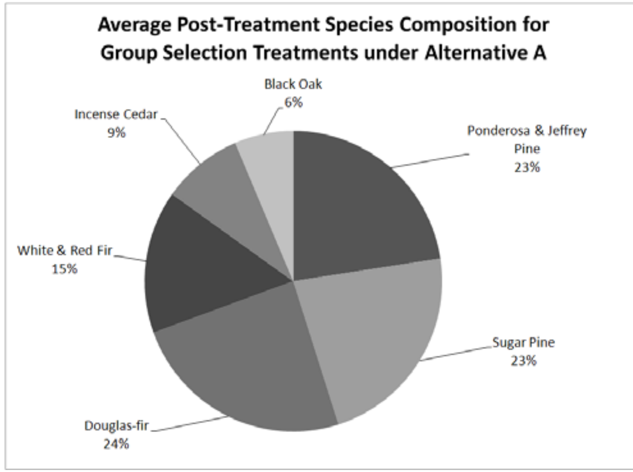

Figure 6. Average Post-Treatment Species Composition for Group Selection Harvest under Alternative A

Landscape Structure and Heterogeneity: Stand Size Class and Density

Group Selection treatments would enhance landscape structure and heterogeneity by converting mid-seral closed-canopy forest dominated by shade-tolerant species to early seral, open canopy gaps which would create favorable conditions for the establishment, growth, and development of shade-intolerant species. Primarily CWHR 4 stands and less desirable areas (in terms of tree size and species composition) within CWHR 5 stands would be converted to areas best characterized by CWHR 1 and 2 stands. Under alternative A, approximately 85 percent of the group selection treatments would occur in CWHR size class 4 stands, and less than 15 percent would occur in CWHR size class 5 stands. Furthermore gaps of openings with tree regeneration are an inherent component of within-stand variability which is thought to be more characteristic of a low to mixed severity, active fire stand structure (North et al. 2009, Collins and Stephens 2010).

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Post-harvest group selection site preparation would be performed, if necessary, to create favorable reforestation conditions. This would also reduce total surface fuel loads in the short-term. However, over the subsequent 20 to 30 years, the establishment and growth of shrub species and sapling/pole-sized trees would create areas of potentially high severity fire behavior.

Predicted flame lengths would exceed the 4 foot threshold for initial attack. Consequently, the probability of torching would increase to 77 percent on average within 30 years resulting in passive crown fire behavior that would result in high levels of basal area mortality. Early seral stands, by nature of their inherent structure, are susceptible to these risks (Thompson et al. 2007); however the scattered, disparate arrangement and small scale of group selection treatments strategically located within DFPZ and Area thinning mechanical thinning treatments mitigates these risks

Direct and Indirect Effects: Herbicide, Borax, and Noxious Weed Treatments

Noxious weeds may compete for water, light, and nutrients with native understory vegetation and tree seedlings which would have a negative effect on native forest vegetation. The treatments proposed in alternative A would have a beneficial effect by controlling the invasion and spread of noxious weeds and reducing competition with native forest vegetation in the analysis area. In particular, noxious weed treatments would have a beneficial effect for tree regeneration, as these treatments would reduce the potential for noxious weed establishment in such early seral, open canopy environments. The removal of noxious weeds by mechanical or chemical method would have a negligible effect on stand- and landscape-level fire behavior and related tree mortality. The target weed species are found in small, isolated populations and are not generally considered unusually flammable.

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Noxious weed treatments and borax treatments would not reduce trees per acre, basal area per acre or relative stand density and consequently would have negligible effects on stand structure.

Species Composition

Noxious weed treatments would have negligible effects on species composition. Borax treatments would prevent the infection of pine stumps by the *Heterobasidion* root disease. Borax treatments would have both short-term and long-term beneficial effects by reducing the potential for ponderosa pine mortality.

Landscape Structure and Heterogeneity: Stand Size Class and Density

Noxious weed treatments and borax treatments would not affect CWHR Size class and density and consequently, would have negligible effects on landscape structure and heterogeneity.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Noxious weed treatments and borax treatments would have negligible effects on fuel loading, predicted flame length, probability of torching, fire type, and basal area mortality, and consequently, would have negligible effects on fuels and potential fire behavior.

Direct and Indirect Effects: Watershed Improvements

Watershed improvements include road decommissioning, maintenance, and road reconstruction. Since these activities are largely restricted to the road prism, the effects to forest vegetation, fuels, and potential fire behavior and effects would be negligible.

Stand Structure: Trees per Acre, Basal Area perAacre, and Relative Stand Density

Watershed improvements would not notably reduce trees per acre, basal area per acre or relative stand density and consequently would have negligible effects on stand structure.

Species Composition

Watershed improvements would have negligible effects on species composition.

Landscape Structure and Heterogeneity: Stand Size Class and Density

Watershed improvements would not affect CWHR size class and density and consequently, would have negligible effects on landscape structure and heterogeneity.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Watershed improvements would have negligible effects on fuel loading, predicted flame length, probability of torching, fire type, and basal area mortality, and consequently, would have negligible effects on fuels and potential fire behavior. However watershed improvements would improve access along roads which could enhance fire suppression efforts in direct and initial attack of wildfire ignitions.

Direct and Indirect Effects: Air Quality

Under alternative A, underburning, pile burning, and mechanical treatments proposed under action alternatives would produce emissions. Please refer to the Direct, Indirect, and Cumulative Effects discussion for Air Quality in the Comparison of Alternatives section.

Cumulative Effects of Alternative A

The cumulative effects of past projects may be characterized by the existing conditions that exist on the landscape today. Present and future projects may be characterized by a shift in land management values and practices that emphasize forest structure (including the retention of large dominant and codominant trees), the importance of species diversity, the role of fire as a process, and their relationship to landscape diversity and healthy, resilient ecosystems.

Due to the nature of the proposed treatments and silvicultural prescriptions, cumulative effects would include the maintenance and development of large trees throughout the analysis area. Upper diameter limits focus on retaining both large dominant and codominant as well as intermediate sized-trees which would maintain the component of large trees that exist in the analysis area. In addition, thinning from below treatments would create conditions favorable for growth and development of large trees.

Snag levels could be reduced in current, proposed, and future fuel reduction projects, therefore the cumulative effect would be the reduction of snags in treated areas to minimum retention levels determined by forest type. However, across the analysis area, snag recruitment would continue to occur, particularly in untreated areas where high stand densities would continue to contribute to mortality. Snag retention guidelines implemented in current, proposed, and future forest management projects (as directed by the 2004 SNFPA (USDA 2004b)) in combination with snag recruitment in untreated areas would contribute to maintaining snags throughout the analysis area.

The cumulative effect of current, proposed, and reasonably foreseeable projects would include maintaining and promoting species diversity, particularly enhancing the regeneration and development of shade-intolerant species. Preference in thinning prescriptions for retaining shade-intolerant species in Sierra Mixed conifer stands and preferential regeneration of shade-intolerant species in group selection units would enhance the regeneration, growth, and development of shade-intolerant species. These treatments would contribute to a higher shade-intolerant species composition in treated areas immediately post-treatment.

Given the current direction in the 2004 SNFPA (USDA 2004b) and the Forest Service's emphasis on ecological restoration through the retention of large trees and thinning primarily small trees, the cumulative effect of, current, proposed, and future forest management projects would be a reduction in

	CWHR 1 & 2 (Seedlings & Saplings)	CWHR 3 (Pole-sized trees)	CWHR 4 (Small Trees)	CWHR 5 (Medium/Large Trees)
All	27.0%			
Dense		-16.5%	-11.6%	-7.6%
Moderate		-7.3%	-7.8%	4.7%
Open		12.1%	22.3%	0.0%
Sparse		0.0%	0.0%	0.0%

Figure 7. Cumulative Effects: Percent Change in CWHR Size Class and Density under Alternative A

stand densities, particularly in the smaller tree sizes. Stand density would be reduced particularly in the smaller diameter classes through all action alternatives. This effect (and the longevity of this effect) differs by alternative due to the differences in amount of acres treated under differing canopy cover retention guidelines.

Figure 7 displays the cumulative effects of percent change in CWHR size class and density under alternative A. Stand structure within treated stands would have lower stand densities and would be characterized by mid- to later-seral open canopy stands. Under alternative A, treatments would contribute to a decrease in mid-seral closed-canopy conditions, primarily in CWHR 4M and 4D, would correspond with 22 percent increase in mid-seral open canopy stands and a 27 percent increase in early seral areas. The horizontal and vertical structure of these stands would be diverse and would be comprised of clumps of trees, gaps in the canopy, and intermingled openings. The intensity of this effect would be limited by the number of acres treated over time and tempered by the development of mid-seral closed-canopy forests in untreated stands; however, alternative A would provide for the greatest reduction in stand density on the stand level and create more open canopy stands that would enhance development of later seral open canopy stands and would be more resistant to the effects of fire, drought, insects, and disease. These open canopy stands would also promote conditions favorable for shade-intolerant species to establish and develop and contribute to species diversity across the landscape. Relative to all alternatives, alternative A provides for the largest change in landscape structural diversity with the greatest longevity of treatment.

Stand-level treatments would reduce potential fire behavior, fire-related tree mortality, and spotting in Fuel Treatment and Area Thinning Units. These treatments would increase the ability of fire management personnel to suppress and contain wildfires during initial and extended operations while increasing firefighter and public safety. At the landscape level, these treatments would provide connectivity between existing fuel treatments on private and public land and break up the continuity of surface and crown fuels. A reduction landscape-level fire-related tree mortality would help maintain stand structure in RHCAs, PACs, and HRCAs in the analysis area.

Alternative C – Non-Commercial Alternative

Treatments and silvicultural prescriptions under alternative C were designed to meet the purpose and need to reduce hazardous fuel accumulations. Treatments focus on reducing surface fuel accumulations and ladder fuels. These treatments would also be compliant with, but generally would not fully implement the standards and guidelines for the Herger-Feinstein Quincy Library Group pilot project area as described in Table 2 of the 2004 Sierra Nevada Forest Plan Amendment ROD (USDA 2004b) Table 31 displays the treatments, prescriptions, and corresponding acres that would be implemented under alternative C.

Table 31. Treatments, Prescriptions, and Corresponding Acres Proposed under Alternative C

Type	Treatment	Prescription	Acres
DFPZ	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	1,026
	Mastication	Rx 6: Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH.	357
	Mechanical Thinning	Rx 8: Thin to 30-40 percent canopy cover, retain live trees greater than or equal to 12 inches DBH; except in CWHR 5M/5D, thin to 40 percent canopy cover, retain live trees greater than or equal to 12 inches DBH; and In RHCA's , thin to 50 percent canopy cover , retain live trees greater than or equal to 12 inches DBH; and underburn.	2,591
	Prescribed Fire	Rx 7: Low to moderate intensity prescribed underburn. Aproximately 73 acres within a spotted owl habitat area (SOHA) would be underburned at low intensity.	1,456
Area Thinning	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	231
	Mechanical Thinning	Rx 8: Thin to 30-40 percent canopy cover, retain live trees greater than or equal to 12 inches DBH; except in CWHR 4M/4D and CWHR 5M/5D, thin to 40-50percent canopy cover , retain live trees greater than or equal to 12 inches DBH; and In RHCA's , thin to 50 percent canopy cover , retain live trees greater than or equal to 12 inches DBH; and underburn.	290

Direct and Indirect Effects: Hand Thinning Treatments

Direct and Indirect effects of hand thinning treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Mechanical Treatments

Mechanical treatments under alternative C would implement a 12 inch upper diameter limit; however canopy cover reduction would follow table 2 standards and guidelines as directed under the 2004 SNFPA. This would allow for canopy cover reductions in CWHR size class 4down to 30 percent canopy cover within DFPZ treatments, and down to 40 to 50 percent canopy cover in area thinning treatments. Table 32 displays the average post-treatment stand attributes of mechanical thinning treatments under alternative C.

Table 32. Average Post-Treatment Stand Attributes of Mechanical Thinning Treatments under Alternative C

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
Rx8	255	-43%	100%	173	-15%	46	16.6	14%

Stand Structure: Trees per acre, Basal Area per acre, and Relative Stand Density

Mechanical treatments would reduce stand density through thinning and removal of conifers up to 12 inches DBH. These treatments would reduce trees per acre by 43 percent, on average, and would range from 13 to 88 percent depending on the individual stand. *Across all stands, 100 percent of the trees* *greater than 12 inches DBH would be retained.* On average, alternative C would retain 255 trees per acre which would consistently have higher tree densities than desired conditions for forest health, and would not resemble forest structure adapted to an active fire disturbance regime.

Basal area per acre would be reduced by 15 percent on average, and basal area reduction would range from 2 to 56 percent depending on individual stand conditions and CWHR type. On average, stands would retain approximately 173 square feet of basal area. *Basal area per acre would be reduced below the 150 square feet per acre threshold in only 36 percent of the treated stands.*

Relative stand densities would be reduced to 46 percent post-treatment, on average. Nearly *62 percent of the stands would NOT have relative stand densities within desired conditions immediately post-treatment.* Approximately 25 to 32 percent of these stands would have higher densities than desired 20 to 30 years in the future and would need to be evaluated for re-treatment.

Species Composition

While mechanical thinning treatments would employ species preference guidelines to enhance species composition of the residual stand, mechanical treatments under alternative C would have lower capacity to affect species composition change because prescriptions that retain trees all trees greater than 12 inches DBH would not affect overstory tree composition. Overstory tree is important because overstory trees have reached reproductive maturity and will produce the majority of seed in the stands for future regeneration. Mechanical thinning treatments under alternative C would not remove undesirable shade-tolerant trees greater than 12 inches DBH, and consequently, would retain shade-tolerant trees that would be a future seed source for more shade-tolerant tree regeneration.

As a result, species stand composition of shade-intolerant species would only increase by 1 percent, on average; however, depending on stand conditions, this increase could be as much as 4 percent or, in the case of 39 percent of the stands, result in a decrease or no change in shade-intolerant species composition.

Landscape Structure and Heterogeneity: Stand Size Class and Density

The average increase in stand quadratic mean diameter would be 14 percent under mechanical thinning prescriptions in alternative C. This increase in stand quadratic mean diameter, however, would not notably enhance the development of CWHR 4 stands into CWHR 5 stands. In thirty years after treatment, only 7 percent of treated stands would have stand quadratic mean diameter of 24 inches or greater which is the threshold used to classify CWHR size class 5.

Canopy cover would be reduced through mechanical treatments; however, since alternative C has a 12 inch upper diameter limit, this reduction in canopy would be limited to primarily understory and mid-story trees. Canopy cover in CWHR 4 stands could be reduced down to 30 percent canopy cover while canopy cover in CWHR 5 stands would be maintained above 40 percent, at a minimum. On average canopy cover would be 44 percent and would range from 33 to 59 percent dependent on individual stand conditions. *Two-thirds of the stands would have greater than 40 percent canopy cover and moderate and dense closed-canopy conditions would be maintained.*

The 12 inch upper diameter limit for mechanical thinning under alternative C would limit opportunities to enhance horizontal and vertical structural heterogeneity best characterized by an open canopy stand with gaps of low densities/canopy cover and clumps of high density/canopy covers. While the mechanical treatments would reduce ladder fuels, but the efficacy to reduce stand densities and associated negative impacts of future fires, drought, and insect and disease occurrences would be notably limited.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Mechanical thinning treatments would primarily reduce ladder fuels, whole-tree yarding would minimize the addition of activity fuels, and follow-up prescribe fire treatments would reduce surface fuels. In combination, these treatments would reduce fuel loadings and predicted flame length, probability of torching, fire type, and basal area mortality of potential future fires. Table 33 displays the average post-treatment fuels and potential fire behavior attributes for mechanical treatments under alternative C.

Table 33. Average Post-Treatment Fuels and Potential Fire Behavior Attributes for Mechanical Treatments under Alternative C

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
Rx8	12	< 1	15	Incidental	23	Surface Fire	13

Fuel loading would be reduced to 12 tons per acre, on average, and would range between 3 and 25 tons per acre. Mechanical treatments alone would compact and crush existing surface fuels and greatly reduce ladder fuels to reduce potential fire behavior prior to prescribe fire treatments. However, the prescribed fire treatments would reduce existing surface fuels even further and allow for the re-introduction of fire into the ecosystem.

Flame lengths would be reduced to well below the 4 foot threshold in 96 percent of the stands which would allow for direct attack utilizing hand crews. The probability of torching would be incidental which would substantially reduce the likelihood of passive crown fire initiation. Potential for torching would be restricted to islands of untreated areas such as control areas and small pitches of steep, untreatable ground.

Potential fire type would be reduced from high severity passive crown fire as sustained under existing conditions to a low severity surface fire due to the treatment’s reduction of surface, ladder, and crown fuels in 96 percent of the stands. Consequently, potential basal area mortality would also be reduced to 13 percent on average, and would range from 6 to 28 percent depending on individual stand conditions.

Direct and Indirect Effects: Mastication Treatments

Direct and Indirect effects of mastication treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Prescribed Fire Treatments

Direct and Indirect effects of prescribed fire treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Group Selection Treatments

Group selection treatments would not occur under alternative C.

Direct and Indirect Effects: Herbicide, Borax, and Noxious Weed Treatments

Herbicide, borax, and noxious weed treatments would not occur under alternative C.

Direct and Indirect Effects: Watershed Improvements

Direct and Indirect effects of watershed improvements would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Air Quality

Under alternative C, underburning, pile burning, and mechanical treatments proposed under action alternatives would produce emissions. Please refer to the Direct, Indirect, and Cumulative Effects discussion for Air Quality in the Comparison of Alternatives section.

Cumulative Effects of Alternative C

Due to the nature of the proposed treatments and silvicultural prescriptions under alternative C, cumulative effects would include the maintenance and development of large trees throughout the analysis area. Upper diameter limits would retain all intermediate and large sized trees including all small trees between 12 and 20 inches DBH, As a result, stand densities would be reduced only in trees less than 12 inches which would only affect densities of understory and some mid-story trees. This effect compromises the ability of these treatments to meet forest health objectives such as improvement of conditions that favor shade-intolerant species, reducing stand densities to desired levels, and creating open canopy stands that contribute to landscape heterogeneity and enhance growth of small and medium sized trees into larger diameter classes.

Snag levels would be maintained due to the 12 inch upper diameter limit and across the project area, snag recruitment would continue to occur where high stand densities would continue to contribute to mortality.

Preference in thinning prescriptions for retaining shade-intolerant species in Sierra Mixed conifer stands would be implemented, however the efficacy of these preference guidelines would be limited by the upper diameter limit. As a result, retention of small and intermediate sized shade-tolerant trees would be retained and the improvement of species composition would be less relative to alternatives A and E. In addition, alternative C does not implement group selection and generally retains higher stand densities and closed canopies on average which would limit the establishment, growth, and development of desirable shade-intolerant species. Over time, these relatively denser and closed canopy conditions would favor shade-tolerant species.

	CWHR 1 & 2 (Seedlings & Saplings)	CWHR 3 (Pole-sized trees)	CWHR 4 (Small Trees)	CWHR 5 (Medium/Large Trees)
All	5.5%			
Dense		-16.5%	-11.6%	-7.6%
Moderate		-7.3%	0.5%	5.2%
Open		12.1%	7.8%	0.0%
Sparse		0.0%	0.0%	0.0%

Figure 8. Cumulative Effects: Percent Change in CWHR Size Class and Density under Alternative C

Figure 8 displays the cumulative effects of percent chance in CWHR size class and density under alternative C. Under alternative C, mid-seral closed-canopy conditions would generally be maintained with the exception of a relatively minor 7.8 percent increase in mid-seral open canopy stands. The 12 inch upper diameter limit would provide for vertical separation between surface and canopy fuels; however, horizontal continuity of closed-canopy stands would be maintained. The homogeneity of these stands would temper the resistance to the effects of fire, drought, insects, and disease. Maintenance of mid-seral closed-canopy stands would not promote conditions favorable for shade-intolerant species to establish and develop and would not notably contribute to species diversity across the landscape. Relative to all alternatives, alternative C provides for a modest change in landscape structural diversity with a lower longevity of treatment.

Stand-level treatments would reduce potential fire behavior, fire-related tree mortality, and spotting in Fuel Treatment and Area Thinning Units. These treatments would increase the ability of fire management personnel to suppress and contain wildfires during initial and extended operations while increasing firefighter and public safety. At the landscape level, these treatments would provide connectivity between existing fuel treatments on private and public land and break up the continuity of surface and crown fuels. A reduction in landscape-level fire-related tree mortality would help maintain stand structure in RHCAs, PACs, and HRCAs in the analysis area.

Alternative D – 2001 SNFPA ROD Consistent Alternative

Treatments and silvicultural prescriptions under alternative D were designed to meet the standards and guidelines for treatments and land allocation which would be compliant with the 2001 Sierra Nevada Forest Plant Amendment ROD (USDA 2001b). These treatments would also be compliant with, but generally would not fully implement the standards and guidelines for the Herger-Feinstein Quincy Library Group pilot project area as described in Table 2 of the 2004 Sierra Nevada Forest Plan Amendment ROD (USDA 2004b). Table 34 displays the treatments, prescriptions, and corresponding acres that would be implemented under alternative D.

Table 34. Treatments, Prescriptions, and Corresponding Acres Proposed under Alternative D

Type	Treatment	Prescription	Acres
DFPZ	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	1,464
	Mastication	Rx 6: Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH.	357
	Mechanical Thinning	Rx 9: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 20 inches DBH; leave 15 percent of the stand untreated; and underburn.	709
		Rx 10: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 20 inches DBH; leave 25 percent of the stand untreated; and underburn.	71
		Rx 11: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 20 inches DBH; except in CWHR 5M/5D, thin to 50 percent canopy cover, retain all live trees greater than or equal to 12 inches DBH; leave 25 percent of the stand untreated; and underburn.	574
		Rx 12: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 12 inches DBH; leave 25 percent of the stand untreated; and underburn.	346
	Prescribed Fire	Rx 7: Low to moderate intensity prescribed underburn. Aproximately 73 acres within a spotted owl habitat area (SOHA) would be underburned at low intensity.	1,456
Area Thinning	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	301
	Mechanical Thinning	Rx 10: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 20 inches DBH; leave 25 percent of the stand untreated; and underburn.	26
		Rx 11: Thin to 50 percent canopy cover, retain all live trees greater than or equal to 20 inches DBH; except in CWHR 5M/5D, thin to 50 percent canopy cover, retain all live trees greater than or equal to 12 inches DBH; leave 25 percent of the stand untreated; and underburn.	140

Direct and Indirect Effects: Hand Thinning Treatments

Direct and indirect effects of hand thinning treatments would be similar in intensity to those described for alternative A; however the number acres that would receive hand thinning treatments would increase by as much as 40 percent. This is due to canopy cover reduction restrictions associated with the SNFPA 2001 ROD (USDA 2001b) which would prohibit mechanical thinning in stands with less than 50 percent canopy cover in CWHR 5M, 5D, and 6 stands, Old Forest Emphasis Areas, California spotted owl home range core areas, and WUI: Threat Zone and General Forest land allocations. Within these areas, the SNFPA ROD 2001 specifies:

> *"In stands that currently have between 40 and 50 percent canopy cover, do not reduce canopy cover except where canopy cover reductions result from removing primarily shade-tolerant trees less than 6 inches DBH." (USDA 2001b, pages A-26, A-41,A-44, A-48, A-49, A-50)*

This would result in approximately 500 acres that would not receive the beneficial effects of mechanical thinning on further reduction of stand density, species composition improvement, and enhancement of landscape structure and heterogeneity.

Direct and Indirect Effects: Mechanical Thinning Treatments

Mechanical thinning prescriptions under alternative D allow removal of conifers up to 20 inches DBH, and retain a 50 percent minimum canopy cover. In addition, the SNFPA 2001 ROD (USDA 2001b) guidelines specify that 10 to 25 percent of the stand is to be left untreated depending on land allocation or CWHR type. A portion of these stands have pre-treatment existing canopy covers that are less than 50 percent canopy cover and under the SNFPA 2001 ROD guidelines, treatment in these stands should be limited to hand thinning shade-tolerant trees less than 6 inches in diameter. Table 35 displays the average post-treatment stand attributes for mechanical treatments under alternative D by prescription.

Table 35. Average Post-Treatment Stand Attributes for Mechanical Treatments under Alternative D by Prescription

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
Rx1	251	-48%	100%	194	-9%	52	15.3	6.4%
Rx10	243	-39%	100%	204	-6%	53	15.6	4.6%
Rx11	316	-33%	100%	194	-9%	52	15.8	6.4%
Rx12	235	-39%	100%	179	-7%	48	16.1	3.7%
Rx9	340	-34%	100%	168	-9%	50	13.5	2.7%
Average	292	-37%	100%	187	-8%	51	15.2	5.0%

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Mechanical treatments would reduce stand density through thinning and removal of conifers up to 12 to 20 inches DBH depending on land allocation; a minimum canopy cover of 50 percent would be retained. These treatments would reduce trees per acre by 37 percent, on average, and would range from 6 to 75 percent depending on the individual stand. *Across all stands, 100 percent of the trees greater than 20 inches DBH would be retained.*

Basal area per acre would be reduced by 8 percent on average, and basal area reduction would range from 1 to 34 percent depending on individual stand conditions and CWHR type. On average, stands would retain approximately 187 square feet of basal area. *Basal area per acre would be reduced below the 150 square feet per acre threshold in only 14 percent of the treated stands.*

Relative stand densities would be reduced to 51 percent post-treatment, on average. Approximately 86 percent of stands *would NOT have relative stand densities within desired conditions immediately post-treatment.* Approximately 32 to 43 percent of these stands would have higher densities than desired 20 to 30 years in the future and would need to be evaluated for re-treatment.

Species Composition

While mechanical thinning treatments would employ species preference guidelines to enhance species composition of the residual stand, mechanical treatments under alternative D would have lower capacity to affect species composition change because prescriptions that retain trees a minimum canopy cover of 50 percent limits opportunities to affect overstory tree composition through tree removal. Overstory tree is important because overstory trees have reached reproductive maturity and will produce the majority of seed in the stands for future regeneration. Mechanical thinning treatments under alternative D would not remove undesirable shade-tolerant trees greater than 20 inches DBH and opportunities to remove trees less than 20 inches would be limited by canopy cover constraints. Consequently, this would retain shade-tolerant trees that would be a future seed source for more shade-tolerant tree regeneration.

As a result, species stand composition of shade-intolerant species would only increase by 1 percent, on average; however, depending on stand conditions, this increase could be as much as 8 percent or, in the case of 50 percent of the stands, result in a decrease or no change in shade-intolerant species composition.

Landscape Structure and Heterogeneity: Stand Size Class and Density

The average increase in stand quadratic mean diameter would be 5 percent under mechanical thinning prescriptions in alternative D. This increase in stand quadratic mean diameter, however, would not notably enhance the development of CWHR 4 stands into CWHR 5 stands. In thirty years after treatment, only 7 percent of treated stands would have stand quadratic mean diameter of 24 inches or greater which is the threshold used to classify CWHR size class 5.

Canopy cover would be reduced through mechanical treatments; however, since alternative D has a 20 inch upper diameter limit AND specifies a minimum canopy cover retention of 50 percent, this reduction in canopy would be limited to primarily understory and mid-story trees. On average canopy cover would be 50 percent and would range up to 66 percent dependent on individual stand conditions. *Moderate and dense closed-canopy conditions would be maintained.*

The 20 inch upper diameter limit, 50 percent canopy cover minimum retention standards, and guidelines specifying that up to 25 percent of stands be left untreated under alternative D would limit opportunities to enhance horizontal and vertical structural heterogeneity best characterized by an open canopy stand with gaps of low densities/canopy cover and clumps of high density/canopy covers. While the mechanical treatments would reduce ladder fuels, the efficacy to reduce stand densities and associated negative impacts of future fires, drought, and insect and disease occurrences would be notably limited.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Mechanical thinning treatments would primarily reduce ladder fuels, whole-tree yarding would minimize the addition of activity fuels, and follow-up prescribe fire treatments would reduce surface fuels. In combination, these treatments would reduce fuel loadings and predicted flame length, probability of torching, fire type, and basal area mortality of potential future fires. Table 36 displays the average post-treatment fuels and potential fire behavior attributes for mechanical thinning treatments under alternative D by prescription.

Table 36. Average Post-Treatment Fuels and Potential Fire Behavior Attributes for Mechanical Thinning Treatments under Alternative D by Prescription

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
Rx1	12	0.5	7	Incidental	19	Surface Fire	14
Rx10	8	3.4	13	27%	18	Surface Fire	22
Rx11	14	3.4	11	37%	19	Surface Fire	21
Rx12	13	3.9	13	33%	21	Surface Fire	19
Rx9	11	2.8	13	32%	21	Surface Fire	21
Average	12	2.9	11	28%	20	Surface Fire	19

Fuel loading would be reduced to 12 tons per acre, on average, and would range between 3 and 27 tons per acre. Mechanical treatments alone would compact and crush existing surface fuels and greatly reduce ladder fuels to reduce potential fire behavior prior to prescribe fire treatments. However, the prescribed fire treatments would reduce existing surface fuels even further and allow for the re-introduction of fire into the ecosystem.

Flame lengths, on average, would be reduced below the 4 foot threshold which would allow for direct attack utilizing hand crews. Approximately 11 percent of the stands would have flame lengths greater than 4 feet primarily due to the amount of fuel loading, and untreated vegetation left in the stand. The probability of torching would be reduced to 28 percent on average which would reduce the likelihood of passive crown fire initiation. Potential for torching would exist in untreated areas such as control areas and small pitches of steep, untreatable ground, and specified untreated areas. In a portion of the stands, the canopy cover retention guidelines simply limit the amount of ladder fuels that can be removed to modify fire behavior.

Potential fire type would be reduced from high severity passive crown fire as sustained under existing conditions to a low severity surface fire due to the treatment’s reduction of surface, ladder, and crown fuels. Consequently, potential basal area mortality would also be reduced to 19 percent on average, and would range from 8 to 32 percent.

Direct and Indirect Effects: Mastication Treatments

Direct and Indirect effects of mastication treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Prescribed Fire Treatments

Direct and Indirect effects of prescribed fire treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Group Selection Treatments

Group selection treatments would not occur under alternative D.

Direct and Indirect Effects: Herbicide, Borax, and Noxious Weed Treatments

Direct and Indirect effects of herbicide, borax, and noxious weed treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Watershed Improvements

Direct and Indirect effects of watershed improvements would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Air Quality

Under alternative D, underburning, pile burning, and mechanical treatments proposed under action alternatives would produce emissions. Please refer to the Direct, Indirect, and Cumulative Effects discussion for Air Quality in the Comparison of Alternatives section.

Cumulative Effects of Alternative D

Due to the nature of the proposed treatments and silvicultural prescriptions under alternative D, cumulative effects would include the maintenance and development of large trees throughout the analysis area. The variable 12 to 20 inch upper diameter limits would retain all intermediate and large sized trees. In addition, the 50 percent canopy cover minimum would maintain closed-canopy conditions. Lastly, under alternative D, 15 to 25 percent of the unit, depending on land allocation, would remain untreated. As a result, stand densities would be reduced only in trees less than 20 inches which would only affect densities of understory and some mid-story trees. This effect (and the longevity of this effect) compromises the ability of these treatments to meet forest health objectives such as improvement of conditions that favor shade-intolerant species, reducing stand densities to desired levels, and creating open canopy stands that contribute to landscape heterogeneity and enhance growth of small and medium sized trees into larger diameter classes.

Snag levels would be maintained due to the 12 inch upper diameter limit and across the analysis area, snag recruitment would continue to occur where high stand densities would continue to contribute to mortality.

Preference in thinning prescriptions for retaining shade-intolerant species in Sierra Mixed conifer stands would be implemented; however the efficacy of these preference guidelines would be limited by the upper diameter limits, the 50 percent canopy cover minimum retention guidelines, and the untreated areas. As a result, retention of small and intermediate sized shade-tolerant trees would be retained and the improvement of species composition would be less relative to other action alternatives. In addition, alternative D does not implement group selection and generally retains higher stand densities and closed canopies on average which would limit the establishment, growth, and development of desirable shade-intolerant species. These relatively denser and closed-canopy conditions would favor shade-tolerant species.

	CWHR 1 & 2 (Seedlings & Saplings)	CWHR 3 (Pole-sized trees)	CWHR 4 (Small Trees)	CWHR 5 (Medium/Large Trees)
All	5.5%			
Dense		-16.5%	-11.6%	-7.4%
Moderate		6.0%	2.6%	4.6%
Open		0.3%	3.2%	0.0%
Sparse		0.0%	0.0%	0.0%

Figure 9. Cumulative Effects: Percent Change in CWHR Size Class and Density under Alternative D

Figure 9 displays the cumulative effect of percent change in CWHR size class and density under alternative D. Under alternative D, mid-seral closed-canopy conditions would be maintained. The 12 inch to 20 inch upper diameter limits would provide for vertical separation between surface and canopy fuels in treated areas, however, horizontal continuity of closed-canopy stands would be maintained. The homogeneity of these stands would temper the resistance to the effects of fire, drought, insects, and disease. Maintenance of mid-seral closed-canopy stands would not promote conditions favorable for shade-intolerant species to establish and develop and would not notably contribute to species diversity across the landscape. Relative to all alternatives, alternative D provides for the most modest change in landscape structural diversity with a lower longevity of treatment.

Stand-level treatments would reduce potential fire behavior, fire-related tree mortality, and spotting in Fuel Treatment and Area Thinning Units. Vertical continuity of surface, ladder, and canopy fuels would be maintained in the units where 15 to 25 percent of the area is left untreated. These treatments would increase the ability of fire management personnel to suppress and contain wildfires during initial and extended operations while increasing firefighter and public safety. At the landscape level, these treatments would provide connectivity between existing fuel treatments on private and public land and break up the continuity of surface and crown fuels. A reduction landscape-level fire-related tree mortality would help maintain stand structure in RHCAs, PACs, and HRCAs in the analysis area.

Alternative E – 2004 SNFPA ROD Consistent Alternative

Treatments and silvicultural prescriptions under alternative E were designed to fully implement standards and guidelines for the Herger-Feinstein Quincy Library Group pilot project area as described in Table 2 of the 2004 Sierra Nevada Forest Plan Amendment ROD (USDA 2004b). Table 37 displays the treatments, prescriptions, and corresponding acres that would be implemented under alternative E.

Table 37. Treatments, Prescriptions, and Corresponding Acres Proposed under Alternative E

Type	Treatment	Prescription	Acres
DFPZ	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	1,026
	Mastication	Rx 6: Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH.	357
	Mechanical Thinning	Rx 13: Thin to 30 – 40 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; except in CWHR 5M/5D, thin to 40 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	2,242
		Rx 14: Thin to 30 – 40 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; except in CWHR 4M/4D and CWHR 5M/5D, Thin to 40-50 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	53
	Prescribed Fire	Rx 7: Low to moderate intensity prescribed underburn. Aproximately 73 acres within a spotted owl habitat area (SOHA) would be underburned at low intensity.	1,456
Area Thinning	**Hand Thinning**	Rx 1: Hand thin, pile, and burn trees less than 8 inches DBH and underburn	231
	Mechanical Thinning	Rx 14: Thin to 30 – 40 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; except in CWHR 4M/4D and CWHR 5M/5D, Thin to 40-50 percent canopy cover, retain all live trees greater than or equal to 30 inches DBH; in RHCAs, thin to 50 percent canopy cover, generally retain live trees greater than or equal to 20 inches DBH; and underburn.	261
Group Selection		Harvest trees less than 30 inches DBH .	326

Direct and Indirect Effects: Hand thinning Treatments

Direct and Indirect effects of hand thinning treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Mechanical Thinning Treatments

Direct and indirect effects of mechanical thinning treatments under alternative E would be similar in scale and intensity to those described in alternative A. However, under alternative E, the upper diameter limit of mechanical thinning in DFPZ and Area thinning units would be 30 inches DBH. Table 38 displays the average post-treatment stand attributes for mechanical thinning treatments under alternative E by prescription.

Table 38. Average Post-Treatment Stand Attributes for Mechanical Thinning Treatments under Alternative E by Prescription

Rx	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
Rx13	178	-59%	73%	144	-27%	37	18.1	24 %
Rx14	204	-44%	91%	164	-14%	41	16.5	15%
Average	183	-56%	73%	148	-25%	38	17.7	22%

Stand Structure: Trees per Acre, Basal Area per Acre, and Relative Stand Density

Mechanical treatments would reduce stand density through thinning and removal of conifers up to 29.9 inches DBH. These treatments would reduce trees per acre by 56 percent, on average, and would range from 20 to 91 percent. The vast majority of the trees removed would be less than 20 inches DBH. *On average, 96 percent of trees greater than 20 inches DBH would be retained. Depending on the individual stand conditions, 73 to 100 percent of the trees greater than 20 inches DBH would be retained.*

On average, basal area per acre would be approximately 148 square feet per acre. Basal area per acre would be reduced by 25 percent on average, and basal area reduction would range from 6 to 57 percent depending on individual stand conditions and CWHR type. *Basal area per acre would be reduced below the 150 square feet per acre threshold in sixty one percent of the treated stands.*

In addition, relative stand densities would be reduced to desirable levels post-treatment, approximately, 38 percent on average. *Sixty one percent of the stands would have relative stand densities within desired conditions immediately post-treatment.* Approximately 7 percent of these stands would have higher densities than desired 20 to 30 years in the future and would need to be evaluated for re-treatment.

Species Composition

Mechanical thinning treatments would employ species preference guidelines to enhance species composition of the residual stand. On average species stand composition of shade-intolerant species would increase by 7 percent; however, depending on stand conditions, this increase could be as much as 30 percent or, in the case of 21 percent of the stands, result in no change in shade-intolerant species composition.

Landscape Structure and Heterogeneity: Stand Size Class and Density

The average increase in stand quadratic mean diameter would be 22 percent under mechanical thinning prescriptions in alternative E. This increase in stand quadratic mean diameter would enhance the development of CWHR 4 stands into CWHR 5 stands. Within 30 years of growth, approximately 39 percent of stands would have stand quadratic mean diameter of 24 inches or greater which is the threshold used to classify CWHR size class 5.

Canopy cover would be reduced through mechanical treatments; however, alternative E provides a range of prescriptions which would create a diverse range in canopy covers. Canopy cover in CWHR 4 stands could be reduced down to 30 percent canopy cover while canopy cover in CWHR 5 stands would be maintained above 40 percent, at a minimum.

The prescriptions for mechanical thinning are designed to create both horizontal and vertical structural heterogeneity best characterized by an open canopy stand with gaps of low densities/canopy cover and clumps of high density/canopy covers. CWHR 4 stands would receive heavier thinning (removal of more trees and canopy cover) to create open canopy stands and enhance diameter growth of residual trees into CWHR 5. CWHR 5 stands would receive lighter thinning (less removal of trees and canopy cover) to maintain closed-canopy stand conditions of later seral stands while reducing ladder fuels and stand density to reduce negative impacts of future fires, drought, and insect and disease occurrences.

Fuels and Potential Fire Behavior: Fuel Loading and Predicted Flame Length, Probability of Torching, Fire Type, and Basal Area Mortality

Mechanical thinning treatments would reduce ladder and canopy fuels, whole-tree yarding would minimize the addition of activity fuels, and follow-up prescribe fire treatments would reduce surface fuels. In combination, these treatments would reduce fuel loadings and predicted flame length, probability of torching, fire type, and basal area mortality of potential future fires. Table 39 displays the average post-treatment fuels and potential fire behavior attributes for mechanical thinning treatments under alternative E.

Table 39. Average Post-Treatment Fuels and Potential Fire Behavior Attributes for Mechanical Thinning Treatments under Alternative E

Rx	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
Rx13	12	< 1	24	Incidental	31	Surface Fire	11
Rx14	13	< 1	17	Incidental	24	Surface Fire	15
Average	12	< 1	22	Incidental	30	Surface Fire	12

Fuel loading would be reduced to 12 tons per acre, on average, and would range between 3 and 26 tons per acre. Mechanical treatments alone would compact and crush existing surface fuels and greatly reduce ladder fuels to reduce potential fire behavior prior to prescribe fire treatments. However, the prescribed fire treatments would reduce existing surface fuels even further and allow for the re-introduction of fire into the ecosystem.

Flame lengths would be reduced to less than 1 foot on average, well below the 4 foot threshold in all stands which would allow for direct attack utilizing hand crews. The probability of torching would be incidental which would substantially reduce the likelihood of passive crown fire initiation. Potential for torching would be restricted to islands of untreated areas such as control areas, small pitches of steep, untreatable ground, and clumps retained with high canopy cover and vertical structure of retained understory trees.

Potential fire type would be reduced from high severity passive crown fire as sustained under existing conditions to a low severity surface fire due to the treatment's reduction of surface, ladder, and crown fuels. Consequently, potential basal area mortality would also be reduced to 12 percent on average, and would range from 4 to 20 percent.

Direct and Indirect Effects: Mastication Treatments

Direct and Indirect effects of mastication treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Prescribed Fire Treatments

Direct and Indirect effects of prescribed fire treatments would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Group Selection Treatments

Direct and Indirect effects of group selection treatments would be similar to those described for alternative A. However, approximately 42 additional acres of group selection would be implemented under alternative E for a total of 326 acres. Under alternative E, approximately 80 percent of the group selection treatments would occur in CWHR size class 4 stands, and approximately 20 percent would occur in CWHR size class 5 stands. In addition, all trees less than 30 inches DBH would be removed from group selection units regardless of species.

Direct and Indirect Effects: Herbicide, Borax, and Noxious Weed Treatments

Herbicide, borax, and noxious weed treatments would not occur under alternative E. Noxious weed populations would have greater potential to spread. The spread of these noxious weeds could complicate future vegetation management activities requiring more mitigation measures to limit the spread of these species.

Borax treatments would also not occur under alternative E. Thinning treatments that do not include borax treatments would increase the probability for the spread and development of new infections of *Heterobasidion* root disease. This could result in increased tree mortality and increased fuel accumulations over time.

Direct and Indirect Effects: Watershed Improvements

Direct and Indirect effects of watershed improvements would be similar in scale and intensity to those described for alternative A.

Direct and Indirect Effects: Air Quality

Under alternative E, underburning, pile burning, and mechanical treatments proposed under action alternatives would produce emissions. Please refer to the Direct, Indirect, and Cumulative Effects discussion for Air Quality in the Comparison of Alternatives section.

Cumulative Effects of Alternative E

Cumulative effects of alternative E would be similar to those described for alternative A, with the exception of group selection treatments. Alternative E would implement 326 acres of group selection

	CWHR 1 & 2 (Seedlings & Saplings)	CWHR 3 (Pole-sized trees)	CWHR 4 (Small Trees)	CWHR 5 (Medium/Large Trees)
All	30.2%			
Dense		-16.5%	-11.6%	-7.6%
Moderate		-7.3%	-8.4%	4.3%
Open		12.1%	20.3%	0.0%
Sparse		0.0%	0.0%	0.0%

Figure 10. Cumulative Effects: Percent change in CWHR size class and density under alternative E

treatments which would provide for a 25 percent increase in CWHR 1 and 2 on NFS lands. Alternative E would contribute to slightly more early seral stage forest habitat than alternative A. This would correspond with a slightly lower increase (17 percent) in mid-seral open canopy stands characterized by CWHR 4P. Figure 10 displays the percent change in CWHR size class and density under alternative E.

Comparison of Effects by Alternatives

Treatments and corresponding direct, indirect, and cumulative effects are compared for all alternatives in the discussion below.

Direct and Indirect Effects: Hand thinning Treatments

Hand thinning treatments would be similar in intensity for all action alternatives, but the scale of these treatments would vary by alternative. Similar acres of hand thinning treatments would occur under alternatives A, C, and E – approximately 1, 257 acres. Alternative D would implement 1,765, approximately 508 acres of additional hand thinning in lieu of mechanical thinning treatments. Under alternative B, hand thinning treatments would not occur.

Table 40. Comparison of Average Post-Treatment Stand Attributes for Hand Thinning Treatments by Alternative

Alternative	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
B (No Action)	359	0%	100%	175	0	61 %	15.8	0%
All Action Alternatives	179	-46%	100%	160	-9%	42 %	16.9	7.3%

Table 41. Comparison of Average Post-Treatment Fuel and Potential Fire Behavior Attributes for Hand Thinning Treatments by Alternative

Alternative	Surface Fuel Load (tons per acre)	Flame Length (feet)	Canopy Base Height (feet)	Probability of Torching	Crowning Index (mph)	Fire Type	Percent Basal Area Mortality
B (No Action)	28	18	5	74%	22	Passive Crown Fire	85
All Action Alternatives	12	< 1	9	Incidental	25	Surface Fire	13

Table 40 and Table 41 display the comparison of average post-treatment stand attributes and fuel and potential fire behavior attributes for hand thinning treatments by alternative.

Direct and Indirect Effects: Mechanical Thinning Treatments

Mechanical thinning treatments would be implemented in all action alternatives, but the scale and intensity of these treatments would vary by alternative. The acres of mechanical thinning treatments by DFPZ and Area thinning types are displayed by alternative in Table 42.

Table 42. Comparison of Acres of Mechanical Thinning Treatments by Alternative

Alternative	Type	Acres	Total Acres
A	DFPZ	2,336	2,598
	Area Thinning	262	
B	n/a	0	0
C	DFPZ	2592	2,882
	Area Thinning	290	
D	DFPZ	1699	1,864
	Area Thinning	165	
E	DFPZ	2295	2,556
	Area Thinning	261	

Alternatives A and E would implement similar amounts of mechanical thinning, but slightly differ due to the amount of group selection treatments which would occur in the “footprint” of the mechanical thinning units. Alternative C would implement the most acres of mechanical thinning because it does not include group selection treatments, which are deducted from alternatives A and E to correct for “double-counting” of acres. Alternative D would implement the least amount of mechanical thinning treatments of all the action alternatives due to factors that include: 1) guidelines for mechanical thinning treatments under the 2001 SNFPA require that 15 to 25 percent of the stand be left untreated, depending on land allocation, and 2) guidelines for mechanical thinning treatments under the 2001 SNFPA prescribe hand thinning treatments in lieu of mechanical treatments for stands with less than 50 percent canopy cover – this would result in 508 acres of mechanical thinning treatments which would be converted to hand thinning treatments. Alternative B would not implement any mechanical treatments.

Mechanical thinning treatments would also vary in intensity between action alternatives. Table 43 displays the comparison of average post-treatment stand attributes for mechanical thinning treatments by alternative.

Table 43. Comparison of Average Post-Treatment Stand Attributes for Mechanical Thinning Treatments by Alternative

Alternative	Post-Treatment Number of Trees per acre	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-treatment Relative Stand Density	Post-treatment QMD	Average Increase in Diameter
A	177	-57%	73%	147	-25%	38	17.7	23.2%
B	513	0%	100%	206	0%	61	14.6	0.0%
C	255	-43%	100%	173	-15%	46	16.6	14.5%
D	292	-37%	100%	187	-8%	51	15.2	5.0%
E	183	-56%	73%	148	-25%	38	17.7	22.1%

Mechanical thinning treatments under alternatives A and E are very similar in effects; while both alternatives would implement similar ranges in canopy cover retention for CWHR types and RHCAs, alternative A would generally retain more intermediate-sized trees, and remove more small diameter sized trees. Alternative E would include slightly more removal of intermediate-sized trees and correspondingly slightly more retention of small diameter-sized trees. These differences, on average, are very slight and would only be discernable on an individual stand basis of a portion of the stands treated.

Under both alternatives A and E, average post-treatment stand conditions would meet desired conditions for stand structure and density, create open-canopy stands, and enhance growth of residual trees into larger diameter classes, thereby promoting the development of later seral stand conditions.

Alternatives C and D would result in relatively less reduction in stand densities and average post-treatment conditions would not meet desired basal area or relative stand density conditions; however this would vary by individual stand conditions. Diameter limits and canopy cover constraints associated with these alternatives limit the capacity and efficacy of these alternatives in meeting the purposes and needs for forest health. As a result, on average, these alternatives maintain more closed-canopy conditions resulting in less opportunity to enhance heterogeneity and relatively less growth and development of later seral conditions. In particular, treatments under alternatives C and D would maintain closed-canopy mid-seral stand conditions resulting in a homogenous landscape condition which is less diverse and resilient to forest disturbances such as drought, insects and disease, and trends such as increasing fire severity (Miller et al. 2009) and climate change (Millar et al. 2007, North and Hurteau 2009, Battles et al. 2008).

Under alternative B, stands would develop untreated which would result in increasing densities and increased risk for tree mortality and high severity effects from potential disturbances such as drought, fire, and insect and disease occurrences.

These changes in density would also have an effect on species composition. Table 44 displays the percent change in shade-intolerant species composition as a result of hand thinning and mechanical thinning treatments.

Table 44. Comparison of Average Post-Treatment Percent Change in Desired Shade-intolerant Species Composition by Alternative and Treatment

Alternative	Average Post-Treatment Percent Change in desired Shade-Intolerant Species Composition			
	Hand thinning Treatments	Mechanical Thinning Treatments	Group Selection Treatments	Total
A	1.2%	6.7%	26.9%	12.2%
B	0.0%	0.0%	0.0%	0.0%
C	1.2%	1.6%	0.0%	1.4%
D	1.2%	1.3%	0.0%	1.3%
E	1.2%	6.7%	13.7%	7.9%

Alternative A would provide for the greatest increase in shade-intolerant species composition as a result of the lower upper diameter limits desired species as well as the preferentially retention of desirable shade-intolerant species under 30 inches diameter within group selection units. Alternative E would also provide a notable increase in shade-tolerant species composition as canopy cover retention and upper diameter limits in mechanical thinning treatments provide the greatest opportunity to preferentially remove relatively larger amounts of shade-tolerant in order to retain desired shade-intolerant species.

Alternatives C and D provide for little increase in shade-intolerant species composition. In alternative C, the 12 inch upper diameter limit reduces the capacity to improve species composition by eliminating the opportunity to remove shade-tolerant trees greater than 12 inches that would compete with shade-intolerant trees. Similarly, under alternative D, the 50 percent canopy cover retention limits, the 20 inch upper diameter limit, and the 15 to 25 percent retention of untreated areas in the stand reduces the capacity to improve species composition by limiting the opportunity to remove shade-tolerant trees that would compete with shade-intolerant trees. Alternative B would not provide opportunities to improve species composition.

For further discussion on stand density, desired and existing conditions for forest structure and health, and climate change with regards to the treatments proposed under the alternatives, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Table 45. Comparison of Average Post-Treatment Fuel and Potential Fire Behavior Attributes for Mechanical Thinning Treatments by Alternative

Alternative	Post-Treatment Surface Fuel Load (tons per acre)	Post-Treatment Flame Length (feet)	Post-Treatment Canopy Base Height (feet)	Post-Treatment Probability of Torching	Post-Treatment Crowning Index (mph)	Post-Treatment Fire Type	Post-Treatment Percent Basal Area Mortality
A	12	< 1	22	Incidental	30	Surface Fire	12
B (No Action)	28	24 - 25	6	77%	18	Passive Crown Fire	84
C	12	< 1	15	Incidental	23	Surface Fire	13
D	12	2 - 3	11	28%	20	Surface Fire	19
E	12	< 1	22	Incidental	30	Surface Fire	12

Under all action alternatives, fuel loading and potential fire behavior would be reduced through a combination of treating surface fuels, ladder fuels, and canopy fuels with varying degree. As shown in Table 45, all action alternatives would improve fuel conditions and potential fire behavior relative to the existing condition which would be expected to persist under alternative B.

Alternatives A and E would provide for the greatest reduction in fuels and fire behavior which include the greatest reduction in canopy fuels – as a result these alternatives have the highest crowning index, the wind speed which would be required for fire to move from crown to crown of individual trees. In both alternatives A and E, flame lengths, canopy base height, torching, crowning index, fire type, and basal area mortality meet desired conditions.

Alternatives C would also meet desired conditions by reducing primarily surface fuels and ladder fuels with some reduction of canopy fuels depending on individual stand conditions.

Alternative C would not reduce canopy fuels as much as alternatives A or E and as a result would have a lower predicted average crowning index – meaning that tree crowns would be relatively closer more indicative of closed-canopy stand conditions. The reduction of stand density would be, in part, due to greater tree mortality incurred through follow-up prescribed fire treatments under alternative C relative to alternatives A and E.

Relative to all action alternatives, alternative D would reduce primarily surface fuels and ladder fuels, with limited amounts of canopy fuel reduction. Alternative D provides the smallest reduction in ladder fuels and potential fire behavior reduction because these mechanical treatments retain a minimum of 50 percent canopy cover, and maintain 15 to 25 percent of the stand in an untreated condition. These factors contribute to higher flame lengths, larger probabilities of torching, and lower crowning indices relative to the other action alternatives.

While all action alternatives met the fuel objectives in terms of reducing potential fire behavior, research indicates that models used to predict potential fire behavior may, in some instances, under predict potential for crown fire behavior (Scott and Reinhardt 2001, Cruz and Alexander 2010). These models are best interpreted in a relative rather than an absolute sense. As a result, while all alternatives are predicted to meet desired conditions, alternatives that create lower canopy covers and reduce stand density (alternatives A and E) would have the greatest potential for limiting crown fire potential relative to alternatives that maintain higher canopy covers and implement lower diameter limits, such as alternatives C and D. This thought is consistent with the latest research on simulating fire and forest dynamics for landscape fuel treatment projects in the Sierra Nevada (Collins et al. In press). Collins et al. (In press) noted that this trend is substantiated by Safford et al. (2009) who found that lighter intensity, hand thinning treatments did not reduce fire severity as effectively as more intensive treatments, particularly in areas where slope may influence fire behavior. In addition, Fule et al. (2006) noted that while treatments with lower diameter limits (such as alternatives C and D) could reduce potential fire behavior, such constraints were found to hinder restoration of forest structure that is better adapted to an active fire regime. Consequently, alternatives A and E would better meet fuel reduction objectives and re-align forest health and resiliency with an active fire disturbance regime than alternatives C and D. For further discussion regarding fuels reduction treatments, desired conditions for forest health, and the interaction between fuels reduction and forest health objectives, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A and B.

In general, the greatest difference in vegetation and fuels treatments between alternatives lies in the mechanical thinning treatments. Amounts of prescribed fire treatments and mastication treatments are identical throughout all action alternatives, and amounts of hand thinning treatments between alternatives A, C, and E are similar. Under alternative D, approximately 508 acres of additional hand thinning treatments would be implemented in lieu of mechanical treatments for stands with less than 50 percent canopy cover. Table 47 displays the comparison of mechanical treatments by alternative using the measurement indicators.

Table 46. Comparison of Mechanical Treatments by Alternative using Measurement Indicators

	Stand Structure & Density				Species Composition	Landscape Structure and Heterogeneity		Fuels and Potential Fire Behavior		
Alternative	Post-Treatment Percent Retention of trees > 20 inches dbh	Post Treatment Basal Area < 150 sq ft. per acre	Post-Treatment Relative Stand Density = 25-40%	Relative Stand Density > 60 % at 20-30 years	Post Treatment % Shade intolerant Species Composition improved	Quadratic Mean Diameter @ 30 yrs > 24 inches dbh (CWHR Size class 5)	Canopy Cover @2010	Post Treatment Flame Lengths less than < 4 ft	Post Treatment Fire type = Surface fire	Post Treatment Basal Area mortality < 25%
A	All stands would retain 73-100% of trees >20"	68% of stands would meet desired conditions	68% of stands would meet desired conditions	7% of stands would exceed the threshold	61% of stands would improve species comp	25% stands would grow into CWHR 5 in 30 years	50% open canopy stands, 50%closed canopy stands	100% of stands meet desired condition	100% of stands would meet desired conditions	100% of stands would meet desired conditions
B	All Stands would retain 100% of trees >20" dbh	17% of stands would meet desired conditions	14% of stands would meet desired conditions	77 - 89% of stands would exceed the threshold	No improvement across any stand	4% of stands would grow into CWHR 5 in 30 years	18% open canopy stands, 82% closed canopy stands	0% of stands meet desired condition	4% of stands would meet desired conditions	0% of stands would meet desired conditions
C	All Stands would retain 100% of trees >20" dbh	38% of stands would meet desired conditions	38% of stands would meet desired conditions	25 - 32% of stands would exceed the threshold	35% of stands would improve species comp	7% of stands would grow into CWHR 5 in 30 years	32% open canopy stands, 68% closed canopy stands	96% of stands meet desired condition	96% of stands would meet desired condition	96% of stands would meet desired condition
D	All Stands would retain 100% of trees >20" dbh	14% of stands would meet desired conditions	14% of stands would meet desired conditions	32 - 43% of stands would exceed the threshold	21% of stands would improve species comp	7% of stands would grow into CWHR 5 in 30 years	18% open canopy stands, 82% closed canopy stands	96% of stands meet desired condition	96% of stands would meet desired condition	86% of stands would meet desired conditions
E	All stands would retain 73-100% of trees >20"	61% of stands would meet desired conditions	61% of stands would meet desired conditions	7% of stands would exceed the threshold	61% of stands would improve species comp	39% stands would grow into CWHR 5 in 30 years	43% open canopy stands, 57% closed canopy stands	100% of stands meet desired conditions	100% of stands would meet desired conditions	100% of stands would meet desired conditions

Direct and Indirect Effects: Mastication Treatments

Mastication treatments would be similar in scale and intensity for all action alternatives. Mastication treatments would not occur under alternative B, the no action alternative.

Direct and Indirect Effects: Prescribed Fire Treatments

Prescribed fire treatments would be similar in scale and intensity for all action alternatives. Prescribed fire treatments would not occur under alternative B, the no action alternative.

Direct and Indirect Effects: Group Selection Treatments

Group selection treatments would occur under action alternatives A and E; however, these treatments would vary primarily in scale. Alternative A would implement 284 acres of group selection whereas alternative E would implement 326 acres of group selection. Group selection units would be located primarily in CWHR 4M stands and would be used to convert to enhance shade-intolerant species composition and promote regeneration of a new age class within areas dominated by shade-tolerant species such as white fir. Group selection under alternative A differs from similar treatments in alternative E by preferentially retaining a portion of the shade-intolerant species as leave trees and structural diversity. Table 47 displays the differences in group selection treatments by alternative.

Table 47. Comparison of Average Post-Treatment Stand Attributes for Group Selection Treatments by Alternative

Alternative	Post-Treatment Number of Trees per acre > 20 inches	Average Reduction of Trees per Acre	Post-Treatment Minimum Retention of Trees >20 inches	Post-Treatment Basal Area per Acre	Average Reduction of Basal Area per Acre	Post-Treatment Relative Stand Density	Post-treatment QMD
A	8	-91%	42%	50	-74%	12	28.6
B	Group Selection treatments would not occur						
C	Group Selection treatments would not occur						
D	Group Selection treatments would not occur						
E	5	-92%	24%	37	-82%	9	30.2

Over the long-term of 20 to 30 years, regeneration of young trees and shrub species in the group selection treatments would be susceptible to higher flame lengths, lower canopy base heights, and higher probabilities of torching which would likely lead to passive crown fire behavior resulting in higher basal area mortality – yet, the potential for this type of fire behavior would be restricted to the ½ to 2 acre group selection units. Early seral stands, by nature of their inherent structure, are susceptible to these risks (Thompson et al. 2007); however the scattered, disparate arrangement and small scale of group selection treatments strategically located within DFPZ and Area thinning mechanical thinning treatments mitigate these risks. In addition, the strategic location of group selections within these mechanical fuel treatments would provide greater opportunities for initial attack fire suppression tactics.

Group selection treatments in both action alternatives A and E would enhance landscape structure, heterogeneity and species composition by creating early seral conditions (characterized by CWHR 1 and

2) that are favorable for the establishment, growth, and development of a new age class of shade-intolerant species. Under alternatives B, C, or D, Group selection treatments would not occur and these benefits would not be realized.

Direct and Indirect Effects: Herbicide, Borax, and Noxious Weed Treatments

Herbicide, Borax, and Noxious weed treatments would occur in similar scale and intensities under alternatives A and D. These treatments would limit the spread of noxious weeds and the infection and spread of *Heterobasidion* root disease. These treatments would result in beneficial effects to forest vegetation by maintaining and enhancing understory species composition of native plant communities and reducing tree mortality and shift in species composition of forested stands.

Alternatives C and E would not implement herbicide, borax, or noxious weed treatments, but would implement site disturbing activities such as hand thinning, mechanical thinning, prescribed burning, mastication, and group selection treatments which would: 1) create disturbed areas where noxious weeds could be introduced or spread and 2) create tree stumps suitable for infection and spread of *Heterobasidion* root disease. This could result in potential negative effects to the native species composition of forested stands and directly result in tree mortality from *Heterobasidion* root disease. Considering that *Heterobasidion* root disease persists in infected sites for as long as fifty years, this could have long-term negative effects for forested stands.

Alternative B would not implement herbicide, borax, or noxious weed treatments and would not implement site disturbing activities. However, the potential for spread of noxious weeds and the negative effects on native understory vegetation would persist. The potential for *Heterobasidion* root disease would be negligible since stump surfaces suitable for *Heterobasidion* infection would not be created.

For further information regarding Heterobasidion rood disease and treatments, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix D.

Direct and Indirect Effects: Watershed Improvements

Watershed improvement treatments would be similar in scale and intensity for all action alternatives. Watershed improvement treatments would not occur under alternative B, the no action alternative.

Direct and Indirect Effects: Air Quality

Burning would occur in hand thinning, mechanical thinning, prescribed fire, group selection, and noxious weed treatments which are displayed on project maps. Within mechanical thinning and group selection treatments, biomass removal would be used to minimize potential ladder fuels that would be underburned. Total emissions by alternative are listed in Table 48.

Table 48. Predicted Emissions for All Alternatives

Alternative	Total PM_{10} Emissions (tons)	Total $PM_{2.5}$ Emissions (tons)	Total PM CH_4 Emissions (tons)	Total CO Emissions (tons)	Total PM CO_2 Emissions (tons)	Total NMHC Emissions (tons)	Total VOC Emissions (tons)	Total Vehicle Emissions[a] (tons)
A	183	161	133	1813	28738	97	237	38
B	0	0	0	0	0	0	0	--
C	181	160	132	1800	28533	96	234	12
D	211	185	156	2096	33251	113	304	11
E	183	161	133	1815	28768	97	238	50
Wildfire	835	751	197	4425	89925	637	1413	--

Note: PM = particulate matter; CH4 = methane; CO2 = carbon dioxide; NMHC = non-methyl hydrocarbon; VOC = volatile organic compound
a. Vehicle Emissions = emissions (dust) from vehicles used during implementation. Assumes an 80 percent reduction in emissions from road surfaces (1.2 pounds per vehicle mile) through implementation of standard road watering procedures. Vehicle miles assumes 20-mile average round trip on dirt roads per load; number of trips determined by data contained in the economic analysis.
b. Wildfire assumes emissions for a 5,593-acre wildfire in the mixed conifer forest type.

All burning would be completed under approved burn and smoke management plans. These smoke management plans would describe Northern Sierra Air Quality Management District regulations for burning activities and associated smoke management, and would detail an implementation schedule, the responsible parties, and monitoring and reporting requirements. Piles would be constructed to minimize mixing of soil and burned under weather conditions that would allow efficient combustion. In terms of actual acres of underburning and pile burning implemented, all treated units would be evaluated after treatment to determine if surface fuels were meeting desired conditions. The units meeting desired conditions may not be burned, thereby decreasing total burned acres and emissions. Implementation of underburning, pile burning, and burning of landing piles would occur over five to seven years as weather conditions and resource availability permit. As a result, annual smoke production from burning activities wou1d result in particulate matter emissions less than the threshold of 100 tons per year for a general conformity analysis.

Implementation of fuel treatments in the Keddie Ridge Project could reduce emissions from future wildfires by reducing their size and intensity. Alternative B, the no action alternative would not implement any emission producing activities; however, for comparison, Table 48 displays emissions assuming a 5,593-acre wildfire burned those acres that would not be treated under the action alternatives. In conjunction with mechanical fuel treatments, underburn activities are expected to reduce accumulated surface and ladder fuels and reduce the “unacceptable risk of wildfire” and related uncontrollable emissions as described in U.S. Environmental Protection Agency (2006).

Due to the dispersed nature of the burn piles, the near complete combustion of piled material, and the control over ignition times to favor good smoke dispersion, it is not anticipated that pile burning would substantially impact the local communities. During underburn and pile burn activities, smoke would likely be visible from Indian Valley and Lake Almanor but would move northeast towards Highway 395, Susanville, and the Honey Lake Valley during the day. At night, inversion could reduce visibility in Indian Valley until late morning when the inversion layer typically lifts (Schoeder and Buck 1974).

Harvesting, biomass removal, and road work would be completed primarily with diesel-powered equipment, including feller bunchers, skidders, tractors, graders, and trucks. This equipment would be inspected to determine equipment (spark arresters, fire extinguishers, and firefighting equipment) compliance with fire safety standards. The condition of emissions control systems of various pieces of equipment would vary by age, maintenance, manufacturer, and past use.

Dust emissions would be spread out during the mechanical treatment implementation period of approximately five years. Dust would be mitigated by road watering and other standard management practices described in contracts (Provisions T-806 and B-5.3).

Serpentine-based soils do occur within the project area in the vicinity of Round Valley Reservoir, and these soils would likely be disturbed by project implementation activities. California Air Resources provide regulations concerning operations on serpentine based soils. Agriculture operations and timber harvesting is exempt under California Air Resource regulations (2002-07-029 Asbestos ACTM for Construction, Grading, Quarrying, and Surface Mining Operations, Section 93105, (c)3; http://www.arb.ca.gov/toxics/atcm/asb2atcm.htm) with the exception of road building. The geology report provides additional treatment design criteria to mitigate exposure to naturally occurring asbestos. Dust would be mitigated by road watering and other standard management practices described in contracts (Provisions T-806 and B-5.3) Activities proposed under action alternatives would follow Region 5 interim draft direction for naturally occurring hazardous minerals as described in the November 12, 2010 Draft Guidance for assessing naturally occurring hazardous minerals in travel management subpart A and other planning documents. These serpentine soils would be mapped and monitored for the presence of naturally occurring asbestos. If naturally occurring asbestos is not present above threshold levels, project implementation activities would occur as planned and would include standard management practices for dust mitigation as discussed above. If naturally occurring asbestos is present in levels above threshold, mitigation measures such as 1) specifying winter season for operations that would minimize dust emissions, 2) specifying respiratory protection equipment and soil moisture conditions to minimize dust exposure, 3) altering treatment type such as converting mechanical thinning to hand thinning in conjunction with other aforementioned mitigations, and/or 4) dropping affected units from implementation.

Cumulative Effects

The cumulative effects of all alternatives on vegetation diversity as examined through changes in CWHR size class and density are displayed in Table 49. While existing conditions serve as the baseline for cumulative effects of past activities within the analysis area, present and future projects would have a minor cumulative effect on change in vegetation throughout the analysis area. These effects are best represented by the no action alternative, alternative B which would not implement any of the treatments proposed under the action alternatives. Alternative B would largely maintain existing conditions of dense, closed-canopy, mid-seral stands which are susceptible to 1) extreme potential fire behavior due to heavy accumulations of surface fuels in combination with a homogeneous continuity of ladder and canopy fuels, and 2) drought, insect and disease driven tree mortality as a result of high stand densities and increased inter-tree competition. It is important to recognize that while alternative B maintains existing conditions, these forested landscapes are dynamic, and maintenance of such homogenous conditions would be relatively unstable and pre-dispose this landscape to rapid change due to high severity disturbance events such as fire, drought, and insect and disease occurrences. Such events like the Moonlight and Antelope Fires of 2007 underscore the scale and severity of disturbances which can occur.

Action alternatives would implement proposed treatments which would further alter the diversity of vegetation on National Forest System Lands within the analysis area and these cumulative effects would vary in intensity and scale dependent on alternative.

Alternatives A and E implement treatments and prescriptions which, in general, allow greater opportunity to create more open canopy, mid-seral stands while maintaining closed-canopy, late seral stands which serve as habitat for late seral dependent species. These effects are displayed by the greater reductions in CWHR 4M and 4D, the greater increase in CWHR 4P, and the maintenance of CWHR 5M. Alternatives A and E also provide for the creation of early seral habitat as displayed by the greater increases in CWHR 1 and 2 size classes. The creation of early seral habitat would provide favorable conditions for the establishment, growth, and development of a new age class of shade-intolerant species which would enhance landscape diversity; however, this effect would come from the conversion of primarily mid-seral stands (CWHR 4) and a minor portion from late-seral stands in CWHR size class 5. Approximately 15 to 20 percent of group selection treatments (38 to 66 acres) would occur in CWHR size class 5 under alternatives A and E, respectively.

Table 49. Comparison of Cumulative Effects: Percent Change of CWHR Size Class and Density Across NFS lands within the Analysis Area by Alternative

CWHR Size Class	CWHR Density	Existing Acres	A	B	C	D	E
CWHR 1 & 2 (Seedlings & Saplings)	All	1321	**27.0%**	**5.5%**	**5.5%**	**5.5%**	**30.2%**

	Sparse	102	0.0%	0.0%	0.0%	0.0%	0.0%
Non-Forest Vegetation Types	n/a	4719	0.0%	0.0%	0.0%	0.0%	0.0%

The treatments employed under alternatives A and E would best meet desired conditions for the Fuels Reduction and Forest Health purposes and needs as described in chapter 1. Particularly, the diverse prescriptions that would be implemented under alternative A would enhance heterogeneity at multiple scales - both the stand and landscape scale – while reducing fuels and potential fire behavior and improving forest stand structure, species composition, and forest health, in general. Alternative A would best meet desired conditions for both the fuels reduction and forest health objectives as described in chapter 1 and would re-align forest structure, composition, and heterogeneity with an active fire disturbance regime which would enhance forest resiliency to trends presented by climate change.

Alternatives C and D implement treatments and prescriptions which, in general, maintain relatively greater closed-canopy conditions in mid-seral and late seral stands. These effects are displayed by the maintenance of moderate canopy cover in CWHR size classes 4 and 5, and the relatively smaller increases in open canopy stands in CWHR size classes 4 and 5. In addition, there would be no cumulative addition in early seral conditions as displayed by CWHR size classes 1 and 2.

Alternatives C and D would meet fuel reduction purposes and needs to varying degrees. Alternative C would allow for greater canopy cover reduction and treat more acres relative to alternative D, which would maintain canopy covers greater than 50 percent and would not implement treatments within 15 to 25 percent of the stands, which limits the capacity to affect ladder fuels. While treatments under alternatives C and D could enhance structural diversity at the stand level depending on individual stand conditions, the capacity of these treatments to enhance heterogeneity and improve species composition are limited by the upper diameter limits and canopy cover restrictions associated with the treatments and prescriptions respective to each alternative. This tempers the efficacy of alternatives C and D to enhance heterogeneity and species composition at the landscape scale. Consequently, this also reduces the effectiveness of alternatives C and D to meet desired conditions under the forest health purpose and need.

For further discussion regarding fuels reduction, forest health, and landscape heterogeneity, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, B, and C.

Cumulative Effects: Air Quality

Potential cumulative emissions of smoke, dust, and greenhouse gases for all alternatives are displayed in Table 50. Action alternatives would cumulatively contribute to emissions within the analysis area primarily by contributing to short-term direct effect primarily through underburning and pile burning associated with project activities. All burning would be completed under approved burn and smoke management plans, and the cumulative total amount of emissions would be spread over project implementation timelines of 5 to 7 years. As a result, annual emissions wou1d be less than the threshold of 100 tons per year for a general conformity analysis.

Table 50. Predicted Cumulative Emissions from NFS Lands within the Analysis Area that Would Occur Over A 7 Year Period

Alternative	Total PM_{10} Emissions (tons)	Total $PM_{2.5}$ Emissions (tons)	Total PM CH_4 Emissions (tons)	Total CO Emissions (tons)	Total PM CO_2 Emissions (tons)	Total NMHC Emissions (tons)	Total VOC Emissions (tons)
A	340	298	255	3385	53741	184	536
B	157	136	122	1572	25003	87	299

D	368	322	278	3668	58255	200	602
E	340	298	255	3387	53772	184	536
Wildfire	1296	1166	306	6868	139556	988	2192

Note: PM = particulate matter; CH4 = methane; CO2 = carbon dioxide; NMHC = non-methyl hydrocarbon; VOC = volatile organic compound

b. Wildfire assumes emissions for an 8,336-acre wildfire in the mixed conifer forest type that would occur within an annual fire season.

Action alternatives and present and future proposed vegetation management projects would implement treatments that would reduce the potential for future related uncontrollable smoke/greenhouse gas emissions from wildfires by reducing available fuels within the project area. These projects could contribute to reducing or limiting emissions from future wildfires by promoting desirable fuel conditions across the landscape and reducing wildfire size and/or intensity. Alternative B, the no action alternative would not implement any emission producing activities; however would also not improve fire hazard or fuel reduction to desirable levels within the project area. Table 50 displays emissions assuming an 8,336-acre wildfire burned those acres that would not be treated under present, proposed, or future vegetation management projects. In combinations, these projects are expected to reduce accumulated surface and ladder fuels and reduce the "unacceptable risk of wildfire" and related uncontrollable emissions as described in U.S. Environmental Protection Agency (2006).

Climate Change Considerations

Forests play a major role in the carbon cycle. The carbon stored in live biomass, dead plant material, and soil represents the balance between CO2 absorbed from the atmosphere and its release through respiration, decomposition, and burning. Over longer time periods, indeed as long as forests exist, they will continue to absorb carbon. Complete quantifiable information about project effects on global climate change is not currently possible and is not essential to a reasoned choice among alternatives. However, based on climate change science, the relative effects of these treatments on the ecosystem carbon cycle are recognized. The positive long-term effects on the carbon cycle of proposed fuel reduction treatments are a good example of this. Given the anticipated increase in large wildfires in California (Calif. Climate Action Team 2009), the action alternatives propose beneficial fuel reduction treatments which could contribute to reducing or limiting emissions, size, and intensity of potential future wildfires.

In addition, action alternatives that implement treatments which meet desired conditions for forest health would enhance growth of large residual trees, reduce stand densities, and improve stand and landscape resiliency to forest disturbances such as insect outbreaks greater than endemic levels and large scale high severity fire, thereby enhancing the potential for carbon sequestration within the project area. These treatments would have long-term beneficial indirect effects which would contribute to beneficial cumulative effects on air quality. For more information regarding climate change trends and how these interact with the proposed alternatives, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A.

Compliance with the Forest Plan and Other Direction

All action alternatives were designed to fully comply with the Plumas National Forest LRMP (USDA 1988) as amended by the Herger-Feinstein Quincy Library Group FSEIS and ROD (USDA 1999a, b; USDA 2003a, b) and the Sierra Nevada Forest Plan Amendment FSEIS and ROD (USDA 2004a, b). All prescriptions comply with table 2 (page 69) of the Sierra Nevada Forest Plan Amendment ROD (USDA 2004b) which provide the standards and guidelines applicable to the HFQLG pilot project area for the life of the pilot project. In addition, prescriptions under all action alternatives are designed to comply with the National Forest Management Act (NFMA) of 1976.

Wildlife – Terrestrial and Aquatic

Introduction

This section presents a summary of the biological assessment / biological evaluation (BA/BE) for the Keddie Ridge Hazardous Fuels Reduction Project and includes complete discussions of possible effects of the proposed project and alternatives on Federal Threatened and Endangered species, Federal Proposed species, Forest Service Sensitive species and Management Indicator Species (MIS). The BA/BE and MIS report (and appendices) are on file at the Mt. Hough Ranger District office and available upon request.

Threatened and Endangered Species

Those species listed under the Federal Endangered Species Act. Threatened species are likely to become endangered throughout all or a significant portion of their range (16 United States Code [USC] 1532).

Endangered species are in danger of extinction throughout all or a significant portion of their range (16 USC 1532).

Candidate Species

A Candidate species is a candidate for listing as a Proposed species. The U.S. Fish and Wildlife Service recently changed its policy on Candidate species—the term "Candidate" now strictly refers to species for which the service has enough information on file to warrant or propose listing the species as Endangered or Threatened.

Forest Service Sensitive Species

Those species, generally Federal Candidates for listing or Species of Concern, that have been designated by the Forest Service as needing special management attention because of viability concerns. The Forest Service manages for these species to ensure they will not require listing as Threatened or Endangered.

Management Indicator Species (MIS)

The MIS are used in project analysis because it is believed their population changes indicate whether management activities are having an effect on the viability and diversity of animal and plant communities. There is one MIS listed as Forest Service Sensitive species—the California spotted owl. This species is addressed in the "Forest Service Sensitive Terrestrial Species" section of this EIS.

Analysis Framework

Guiding Regulations

The Keddie Ridge Project is designed to fulfill wildlife management direction specified in the National Forest Management Act of 1976 and the 1988 Plumas National Forest Land and Resource Management Plan (PNF LRMP), as amended by the 1999 Record of Decision on the Herger-Feinstein Quincy Library Group (HFQLG) final environmental impact statement (EIS) and the 2004 Record of Decision on the Sierra Nevada Forest Plan Amendment (SNFPA) Final Supplemental EIS (USDA 1988, 1999b, 2004a,b). Additional management direction for Threatened, Endangered, Candidate, Sensitive, Management Indicator, and migratory bird species on the Plumas National Forest can be found in the following documents:

- Code of Federal Regulations (23, 36, 50 CFR)
- Forest Service Manual and Handbooks (FSM/H 1200, 1500, 1700, 2600)
- Endangered Species Act of 1976
- National Environmental Policy Act (NEPA) of 1969
- National Forest Management Act of 1976
- USDA Forest Service Region 5 Best Management Practices
- Regional Forester (Region 5) Sensitive Animal Species List (June 10, 1998), updated October 2007
- Bald and Golden Eagle Protection Act of 1940
- MIS Analysis and Documentation in Project-Level NEPA, R5 Environmental Coordination (2006)
- Sierra Nevada Forests Management Indicator Species (SNF MIS) Amendment ROD (2007)
- Sierra Nevada Forests Bioregional Management Indicator Species (MIS) Report (2008)
- Migratory Bird Treaty Act of 1918

- Memorandum of Understanding between the US Department of Agriculture Forest Service and the US Fish and Wildlife Service to promote the conservation of migratory birds (2008)

Effects Analysis Methodology

Geographic Area Evaluated for Impacts on Wildlife

Aquatic Wildlife

The “aquatic wildlife species analysis area” geographic boundary was delineated based on the potential direct, indirect, and cumulative effects on aquatic resources. The analysis area for aquatic wildlife species is the same as the “Watershed Analysis Area” used for the cumulative watershed effects analysis as described in the “Hydrology and Soils” section of this chapter. All potential direct, indirect, and cumulative effects on aquatic species would occur within the Watershed analysis area.

Terrestrial Wildlife

The “Wildlife Analysis Area” boundary for terrestrial wildlife was delineated based on the potential direct, indirect, and cumulative effects on California spotted owl protected activity centers (PACs), home range core areas (HRCAs), and breeding home range distribution. The average home range of the owl is representative of the home range of other terrestrial species analyzed in this document using similar habitats (CWHR 4M, 4D, 5M, 5D, and 6), and therefore effects to the owl at this spatial scale would be indicative of the effects to other late seral stage species. The wildlife analysis area extends to a point at which no direct or indirect effects would be discernable and would not act cumulatively with other actions. The wildlife analysis area (115,185 acres) extends beyond the Keddie Ridge Project area (which is approximately 103,309 acres). Of these 115,185 acres, 66,040 acres (57 percent) are National Forest System lands and 49,145 acres (43 percent) are private lands within the wildlife analysis area.

Duration of Impacts

The direct effects would likely be limited to the project implementation phase. Indirect effects would last beyond the implementation period and occur within the temporal bound of the cumulative effects analysis. Cumulative effects are based on past actions that have occurred in the Keddie Ridge Project area since 1979 (for which there is some information available on the effects of wildlife), and carried forward for 50 to 100 years to reflect the potential long-term effects of the proposed Keddie Ridge Project vegetation treatments.

Forest Vegetation

Forest-wide vegetation typing into California Wildlife Habitat Relationships (CWHR) classifications (Mayer and Laudenslayer 1988) was done for the Plumas-Lassen Administrative Study in 2002 (Vestra 2002). This vegetation layer was updated after the Moonlight Fire of 2007, which affected six percent of the wildlife analysis area. The Vestra vegetation map layer, as it is known, did not include thirteen percent (over 14,000 acres) of the analysis area. The HFQLG 2005 Vegetation Mapping Project mapped areas on the forest not covered by Vestra. These two maps were combined in a GIS to provide a complete map of the existing vegetation within the analysis area. All vegetation information is displayed using the CWHR vegetation codes and serves as the baseline acres for analysis. Other sources of information used in the assessment of effects were aerial photos, data generated from common stand exam plots, and field reconnaissance.

Indicator Measures

Indicator Measure: Acres of treatment within riparian habitat conservation areas (RHCAs) and the resulting percent of threshold of concern (TOC) in relation to stream condition. Implementation of ground-disturbing activities in watersheds that are approaching or over the TOC could increase the risk of adverse effects and cumulative watershed effects.

California Spotted Owl—Indicator Measure: Acres were used as the indicator measure to show the effects of the proposed action and alternatives on changes of availability of suitable California spotted owl habitat.

Northern Goshawk—Indicator Measure: Acres were used as the indicator measure to show the effects of the proposed action and alternatives on changes of availability of suitable northern goshawk habitat.

Mesocarnivores—Indicator Measure: Acres of suitable habitat and habitat connectivity were the indicator measures used to show the effects of the proposed action and alternatives on Pacific fisher and American marten habitat and connectivity.

Affected Environment

Federally Threatened and Endangered Species

A list of Threatened and Endangered species was provided by the “Federal Endangered and Threatened Species that may be affected by Projects in the Plumas National Forest”, updated April 29, 2010, accessed via United States Fish and Wildlife Service (USFWS) county list web page (http://www.fws.gov/sacramento/es/spp_lists/auto_list_form.cfm). Based on this list, and information regarding range of species, presence of species or presence of species suitable habitat within project area, it is determined that the Keddie Ridge Project would have no affect on the two Federally listed species present on the Plumas National Forest. There are no Federally Proposed species identified by the USFWS as occurring on the PNF. Table 51 displays Federally-listed species affects determinations.

Table 51. Federally-Listed Species Affects Determinations

Scientific Name	Common Name	Suitable Habitat in area	Observed in Project area (Y/N)	Finding
Desmoceras californicus dimorphus	Valley Elderberry Longhorn Beetle	No	No	No effect
Rana aurora draytonii	California Red-legged Frog	No	No	No effect

USDA Forest Service R5 Sensitive Species

The Keddie Ridge Hazardous Fuels Reduction Project Wildlife Biological Assessment / Biological Evaluation (BA/BE) (USDA 2011b) provides a discussion of the affected environment for all sensitive wildlife species analyzed for the Keddie Ridge Project. The BA/BE is located in the Keddie Ridge Project record, and the analysis of effects on the species identified in Table 52 is incorporated by reference. The bald eagle, California spotted owl, northern goshawk, American marten, Pacific fisher, and Mountain yellow-legged frog are highlighted in this Keddie Ridge Project EIS because of the potential direct, indirect, and cumulative impacts of the proposed action and alternatives on their habitat.

Table 52. Forest Service Region 5 Sensitive Terrestrial Wildlife Species that Potentially Occur on the Plumas National Forest

Species	Category
Birds	
Bald Eagle (Haliaeetus leucocephalus)	Sensitive
American peregrine falcon (Falco peregrinus anatum)	Sensitive
Northern goshawk (Accipiter gentilis)	Sensitive
California spotted owl (Strix occidentalis occidentalis) [a]	Sensitive
Great gray owl (Strix nebulosa)	Sensitive
Willow flycatcher (Empidonax trailii brewsteri)	Sensitive
Greater sandhill crane (Grus canadensis tabida)	Sensitive
Swainson's hawk (Buteo swainsoni)	Sensitive
Mammals	
Sierra Nevada red fox (*Vulpes vulpes necator*)	Sensitive
American marten (*Martes americana*)	Sensitive
Pacific fisher (*Martes pennanti pacifica*) b	Sensitive
California wolverine (*Gulo gulo luteus*)	Sensitive
Pallid bat (*Antrozous pallidus*)	Sensitive
Townsend’s big-eared bat (*Corynorhinus townsendii*)	Sensitive
Western red bat (*Lasiurus blossevillii*)	Sensitive
Amphibians and Reptiles	
Mountain yellow-legged frog (*Rana muscosa*) b	Sensitive
Foothill yellow-legged frog(*Rana boylii*)	Sensitive
Northern leopard frog (*Rana pipiens*)	Sensitive
Northwestern pond turtle (*Clemmys marmorata marmorata*)	Sensitive
Fish	
Hardhead (*Mylopharodon conocephalus*)	Sensitive

Notes:
a. Plumas National Forest Management Indicator Species
b. Pacific fisher, wolverine, and mountain yellow-legged frog designated as Candidate species for listing under the Endangered Species Act.

Bald Eagle

There is one known nesting territory in the Keddie Ridge Project wildlife analysis area, the Round Valley territory, located on the west side of Round Valley Reservoir. This territory was discovered active as early as 1960 but nest monitoring and productions data was not recorded prior to 1971. Since 1971 nesting chronology has been well documented by monitoring activity conducted by California Department of Fish and Game and U.S. Forest Service biologists. Between 1971 and 2010, the one primary nest tree in this territory has produced a total of 39 fledglings. A Bald Eagle Management Area

(BEMA) was identified for habitat allocation in 1988 (USDA 1988) to provide sufficient nesting and foraging habitat to the breeding eagle pair. It is suspected, based on 39 years of monitoring this site, that the adult eagles are non-migratory, staying within the Bald Eagle Management Area (BEMA) (USDA 1988) year round. When the reservoir freezes up, Indian Valley and Indian Creek, both approximately 2 miles east and south respectively, become important forage areas.

California Spotted Owl

Habitat Use and Management Direction—Habitat suitability standards for the California spotted owl (CSO) have been described in a number of sources, including the California spotted owl (CASPO) Interim Guidelines (USDA 1993a), the 1999 HFQLG Final EIS (USDA 1999a), the 2001 SNFPA final EIS (USDA 2001a), the 2004 SNFPA Final Supplemental EIS (USDA 2004a), and the 2004 SNFPA Record of Decision (USDA 2004b).

Stands suitable for nesting and roosting have (1) two or more canopy layers; (2) dominant and co-dominant trees in the canopy averaging at least 24 inches diameter at breast height (DBH); (3) at least 70 percent total canopy cover (including the hardwood component); (4) higher than average levels of very large old trees; and (5) higher than average levels of snags and downed woody material (USDI 2006). The CWHR size classes 5M and 5D (M = moderate; D = dense) have the highest probability of providing stand structures associated with preferred nesting, roosting, and foraging. The threshold canopy cover value that contributes to or detracts from occurrence and productivity is a value near 50 percent (USDA 2001a, Hunsaker et al. 2002). For the Keddie Ridge Project, all of the CWHR 5M size-density classes are considered spotted owl nesting habitat.

Suitable foraging habitat is found in the same forest types listed above for nesting habitat (CWHR classes 5D and 5M), as well as class 4D (trees 11 to 24 inches DBH with dense canopy (60 to 100 percent), and class 4M (trees 11 to 24 inches DBH and moderate canopy cover between 40 and 59 percent). The stands considered to be suitable for foraging have at least two canopy layers, dominant and co-dominant trees in the canopy averaging at least 11 inches DBH, at least 40 percent canopy closure, and higher than average levels of snags and downed woody material (15- to 30-square-foot basal area in snags, 10 to 15 tons per acre downed woody debris) (Verner et al. 1992). Although canopy cover down to 40 percent is suitable for foraging, it appears to be only marginally so (based on owl occurrence and productivity threshold at around 50 percent canopy cover [ibid.]). In its most recent notice concerning the California spotted owl, the USFWS states that owl foraging habitat “is generally described as stands of trees 30 centimeters (12 inches) in diameter or greater, with canopy cover of 40 percent or greater” (USDI 2006), with no other habitat parameters for foraging habitat described. Thus, there appears to be an element of uncertainty associated with what constitutes foraging habitat. For this Keddie Ridge Project analysis, all class 4M are considered owl foraging habitat. In the red fir type, stands with 30 percent or greater canopy cover should be considered suitable for foraging (USDA 2001a).

Table 53 summarizes the potential acres of suitable spotted owl habitat on National Forest System lands in the wildlife analysis area. Suitable CWHR types (USDA 2001a) are Sierra mixed conifer, white fir, red fir, montane hardwood-conifer, montane hardwood, ponderosa pine, montane riparian, lodgepole pine, and eastside pine.

Table 53. Potential Acres of Suitable Spotted Owl Habitat in the Keddie Ridge Project Wildlife Analysis Area

CWHR Type	Habitat Type	National Forest System Acres in Wildlife Analysis Area
4M	Foraging	18,865
4D	Foraging	7,485
5M	Nesting	9,051
5D	Nesting	5,969
Total	Suitable	41,370

The SNFPA Record of Decision (USDA 2004b) management strategy and direction for the California spotted owl recognizes two land allocations with discretely mapped areas, the nest area, or PAC, and the HRCA. Land allocation direction for HRCAs on the Mt. Hough Ranger District include the 300-acre PAC, plus an additional 700 acres of the best habitat available within a 1.5-mile radius of the activity center for a total of 1,000 acres. The direction in the 2004 SNFPA Record of Decision allows for full implementation of HFQLG Pilot Project activities within HRCAs that are established in the HFQLG Pilot Project area until the conclusion of the HFQLG Act in 2012. When the Pilot Project concludes, management direction associated with the HRCA designations will apply to the Plumas National Forest. Therefore, this analysis assesses the impacts of the proposed action and alternatives on HRCAs and suitable spotted owl habitat.

The comprehensive adaptive management strategy to investigate the effects of fuels treatments and group selection silviculture on California spotted owl viability is referred to as the Plumas-Lassen Administrative Study (PLAS). The Administrative Study is being conducted as a collaborative effort by the Forest Service Pacific Southwest Research Station (at Sierra Nevada Research Center); the Universities of California at Berkeley and Davis; and Point Reyes Bird Observatory to determine the long-term effects from forest management practices on spotted owl, song birds, and small mammals. The study will identify the response of these old-forest-dependent species to changes in vegetation composition, structure, and distribution over space and time. When the PLAS began in 2003, the study areas chosen to collect CSO data were all located on the Plumas National Forest. In 2005, the Lassen Demographic Study Area and Plumas NF Survey Areas were fully integrated to define the overall PLAS project area and provide consistent CSO survey effort across the HFQLG project area.

Portions of four PLAS study areas (SAs) are located in the Keddie Ridge Project analysis area. Study areas SA-2 and SA-3, located in the west and southwest portion of the analysis area, have been surveyed since 2003. SA-7 was added in 2009 to encompass the Empire Project area, a portion of which is located in the southern portion of the wildlife analysis area. The Moonlight and Antelope Complex fire study area was added to the PLAS in 2008 to collect information on the association between CSOs and wildfire. This study area makes up a large portion of the northeastern wildlife analysis area and was surveyed again in 2009. Together, these four PLAS areas take in 33,515 acres (29 percent) of the Keddie Ridge Project analysis area.

Spotted owl surveys have occurred in the wildlife analysis area and project area. In 2006 and 2007 the Keddie Ridge Project area was surveyed (Silva_Environmental 2007) following the Protocol for Surveying for spotted owls in Proposed Management Activity Areas and Habitat Conservation Areas (USDA 1993b). As mentioned earlier, four PLAS study areas fall within a portion (29 percent) of the analysis area. SA-2 and SA-3 have been surveyed from 2003-2010. The Moonlight and Antelope Complex fire study area was surveyed in 2008 and 2009. The Empire Project study area (SA-7) was surveyed in 2009 and 2010. PLAS CSO surveys planned for 2011 will include SA-2, SA-3, and SA-7.

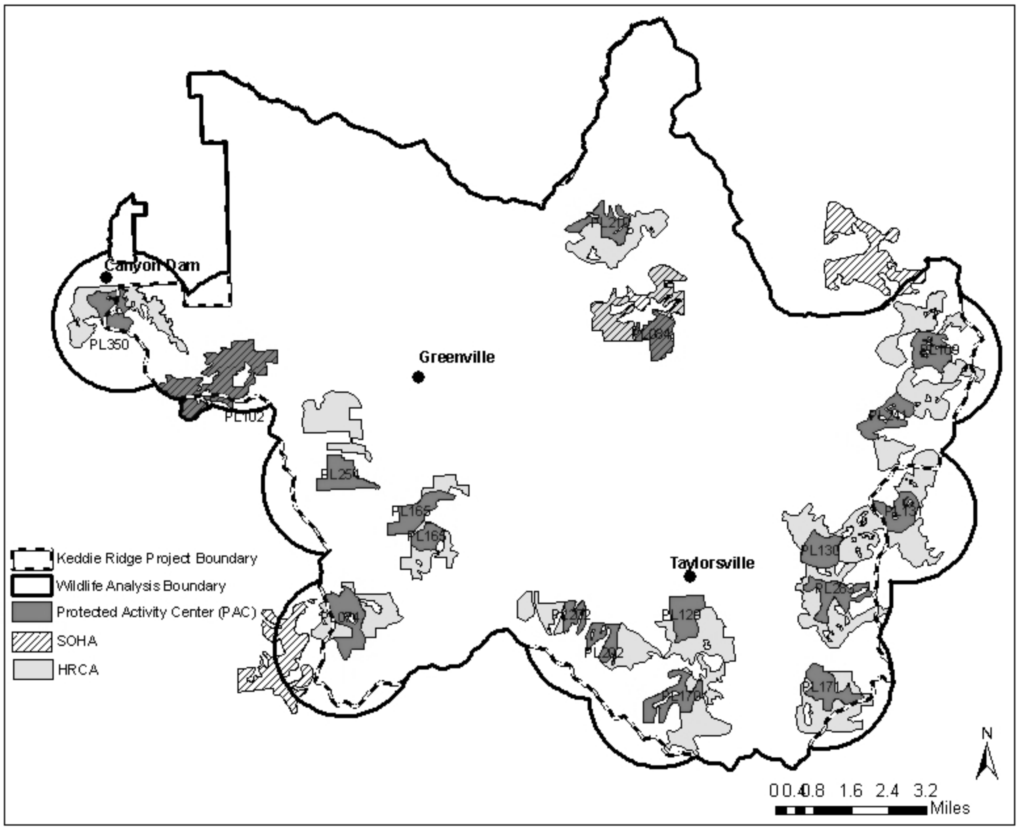

Figure 11. Spotted Owl PACs, SOHAs, and HRCAs in the Keddie Ridge Project Wildlife Analysis Area

Protected Activity Centers and Home Range Core Areas—There are a total of 16 PACs and associated HRCAs in the wildlife analysis area, including all or a portion of four SOHAs (Figure 11). Two spotted owl PACs (PL084, PL131) are located in the project area that could potentially incur direct habitat impacts due to proposed Keddie Ridge Project underburning. Nine associated HRCAs could potentially be directly affected by project activities. The remaining 14 PACs and 6 HRCAs within the wildlife analysis area could be indirectly affected by proposed actions but not directly affected by habitat change as a result of project implementation. Acreages, best detection dates, and current status (based on the most recent surveys to date) for all 16 PACs within the analysis area can be found in Attachment 5 of the Keddie Ridge Project BA/BE.

Areas of Concern—The CASPO Technical Report (Verner et al. 1992) identified Areas of Concern (AOC) within the range and distribution of the California spotted owl. These AOC's are identified simply to indicate potential areas where future problems may limit owl populations and where future problems may be greatest if the owl's status were to deteriorate. Two AOC's identified in the CASPO Report are adjacent to the Plumas National Forest (page 46-49 of the CASPO Report):

- Area of Concern 1: In Lassen County, within the Lassen National Forest and adjacent to the Plumas National Forest. The reason for the concern is that the habitat in this area is discontinuous, naturally fragmented, and poor in quality due to drier conditions and lava-based soils.
- Area of Concern 2: In northern Plumas County, within the Lassen National Forest. The reason for the concern is a gap in known distribution, mainly on private lands, which extends east to west in a band almost fully across the width of the owl's range.

A portion of Area of Concern 2 is located in the wildlife analysis area. The boundaries drawn for this small, narrow section of AOC 2 was based solely on the map provided in the CASPO Report (pg. 47). AOC boundaries in that map, were extremely broad, displayed at the state level scale, and the method used to define boundaries remains unclear (Gould 2008). This roughly 2.25 mile wide band of AOC 2 extends west and northwest of Greenville and lies outside of all proposed activities and would not be directly affected by the Keddie Ridge Project.

Northern Goshawk

The latest published information regarding the goshawk, in terms of population status, distribution, population and habitat trends, and species requirements can be found in the 2001 SNFPA final EIS (USDA 2001a), and in the 2004 SNFPA Final Supplemental EIS (USDA 2004a). A total of 588 northern goshawk breeding territories have been reported from Sierra Nevada National Forests. The Plumas National Forest supports approximately 149 goshawk territories—this is approximately 25 percent of the total number of breeding territories in the Sierra Nevada. These numbers represent goshawks that have been found as a result of both individual project inventories following standardized protocols, as well as nest locations found by other incidental methods. The 1988 Plumas National Forest Land and Resource Management Plan (USDA 1988) calls for a network of 60 nesting territories to provide for the viability of the goshawk. The Plumas National Forest has been developing territories (pre-SNFPA), and now there are 200-acre PACs (USDA 2004a) designated for all newly discovered goshawk breeding sites. Therefore, it is believed that the current density of goshawk territories is contributing to goshawk viability within the Plumas National Forest.

The population trends of northern goshawks in the Sierra Nevada are unknown, although numbers are suspected to be declining due to habitat reductions and loss of territories to timber harvest (Bloom et al. 1986 in USDA 2001a). Based on numerous studies (Bloom et al. 1986; Reynolds et al. 1992; Kennedy 1997; Squires and Reynolds 1997; Smallwood 1998; DeStefano 1998—all citations are in USDA 2001a), there is concern that goshawk populations and reproduction may be declining in North America and California due to changes in the amount and distribution of habitat or reductions in habitat quality. Goshawk surveys were conducted in the Keddie Ridge Project wildlife analysis area in 2006 and 2007 by contractors (Klamath Wildlife Resources and MGW Biological) following methodologies for broadcast acoustical surveys as described in the Forest Service Regions 5 Northern Goshawk Survey Protocols

(USDA 2000b). Approximately 453 call points were surveyed twice in each year. Two new goshawk nesting sites were located, and corresponding 200-acre PACS for these territories were established. A total of 8 goshawk PACs are present on National Forest System lands within the wildlife analysis area. All but one (Canyon Dam PAC) fall completely within this boundary.

The northern goshawk requires mature conifers and deciduous forests with large trees, snags, and downed logs; dense canopy closure for nesting and forests with moderately open overstories; open understories interspersed with meadows, brush patches, or other natural or artificial openings; and riparian areas for foraging (USDA 2001a). Recent studies indicate that goshawks typically select canopy closures greater than 60 percent for nesting (Hall 1984, Richter and Calls 1996, Keane 1997). The following affected CWHR types provide high nesting habitat capability: Sierra mixed conifer, white fir, montane hardwood-conifer, lodgepole pine, montane riparian, ponderosa pine, and montane hardwood (CWHR size and density classes 5D, 5M, 4D, 4M). The following CWHR types are rated as providing moderate nesting habitat capability: aspen (4D, 4M, 5D, 5M), red fir (4D, 4M), and eastside pine (5D, 5M, 4D, 4M) (USDA 2001a). There are approximately 40,935 acres of northern goshawk habitat in the wildlife analysis area that provide high nesting habitat capability and an additional 400 acres that provide moderate nesting habitat capability.

Table 54. High and Moderate Capability Northern Goshawk Nesting Habitat in the Wildlife Analysis Area (National Forest System Acres)

CWHR Size/Density Class	Nesting Habitat Capability	National Forest System Acres in Wildlife Analysis Area
4M	High	18,690
4D	High	7,303
5M	High	8,997
5D	High	5,945
Subtotal	**High**	**40,935**
Eastside Pine 4M/4D/5M/5D	Moderate	52
Red Fir 4M/4D	Moderate	348
Subtotal	**Moderate**	**400**
Total	**All Nesting**	**41,336**

Mesocarnivores (Pacific Fisher and American Marten)

The Plumas National Forest has mapped a forest carnivore network across the Forest that consists of scattered known marten sightings, large habitat management areas, and wide dispersal or connecting corridors. The SNFPA standards and guidelines for mesocarnivore habitat do not speak to carnivore networks, allowing each National Forest to decide on the management need for the network. The Plumas National Forest carnivore network is not incorporated into the Forest Plan as a land allocation with standards and guidelines; rather, it is a plan to evaluate impacts of specific projects on habitat connectivity. The management intent of the network is to provide a continuously connected system of habitats focused on the needs of marten and fisher. This corridor is designed to provide a habitat connectivity corridor linking the Tahoe National Forest with the Lassen National Forest. However, there is concern for corridors between these reserves that allow immigration and emigration to maintain healthy populations. Approximately 13,153 acres (3 percent) of the forest carnivore network are within the wildlife analysis area.

Approximately 50 percent of the Plumas National Forest has been systematically surveyed to protocol using track plates and camera stations (Plumas GIS database). To date, there have been no fisher, Sierra Nevada red fox, or California wolverine detections associated with these surveys. On the Plumas National Forest, all but five sightings of marten occurred within the Lakes Basin-Haskell Peak area or around Little Grass Valley Reservoir. The additional five sightings are unverified reports (verified report consists of photograph, tracks, hair sample, and sighting by a reputable biologist).

Portions of the wildlife analysis area have been surveyed several times for mesocarnivores, beginning in the mid-1980's, using both camera stations and track plates. This includes survey efforts by private contractors and Forest Service crews, as well as survey efforts completed under the PLAS small mammal study module. A total of 181 stations have been surveyed with no mesocarnivores detected to date in the wildlife analysis area. The most recent mesocarnivore surveys in the wildlife analysis area were in 2001, for the Moonlight-Jura DFPZ project, and in 2003, for PLAS study areas 9 and 10.

Pacific Fisher—The USFWS completed an initial 90-day review of a petition submitted by 20 groups seeking to list the Pacific fisher as Endangered in Washington, Oregon, and California. After reviewing the best available scientific information, the USFWS found that substantial information indicated that listing the Pacific fisher as Endangered in its West Coast range may be warranted (USDI 2004). After a 12-month status review, the West Coast population of the fisher was designated as a Candidate species by USFWS (ibid), but listing under the Endangered Species Act is precluded by other higher-priority listing actions.

The current distribution of Pacific fisher in California suggests that the once continuous distribution is now apparently fragmented into two areas separated by a distance that greatly exceeds reported fisher dispersal ability. The methods used to detect fisher in numerous survey efforts have failed to detect this species in an area between Mount Shasta and Yosemite National Park (Zielinski et al. 1995). These authors strongly suggest that the absence of fisher detections within this large 240-mile area is because they do not occur in the areas surveyed. This gap in distribution may be effectively isolating the southern Sierra Nevada population from the rest of the fisher range in Northern California. Since 1990 there have generally been no detections or confirmed sightings of fisher within this 240-mile gap of the Sierra Nevada (note: gap equates to 240 miles as identified in the 2001 SNFPA and 260 miles in the April 8, 2004, Federal Register). The Keddie Ridge Project area is located within this "gap."

A joint partnership between the California Department of Fish and Game, Sierra Pacific Industries (SPI), U.S. Fish and Wildlife Service, and North Carolina State University has embarked on a fisher re-introduction effort within the distribution gap discussed above, specifically within SPI's Sterling Management Tract (Butte County). The Forest Service Pacific Southwest Region supports this reintroduction and is actively pursuing partnerships in this effort as a feature of the SNFPA management strategy (USDA 2004a). The SPI lands in which these fisher re-introductions have taken place are approximately 30 miles to the west-southwest of the Keddie Ridge wildlife analysis area. This re-introduction effort began during November 2009 with a total of 13 animals being released onto SPI lands. In 2010 an additional 15 animals were released. Monitoring data also shows the majority of all individual fisher movements since their release have been on private lands (A. Facka, personal communication, March, 2011). Detections of released fishers on public lands (both the Lassen and Plumas National Forests) have primarily been from dispersing males, all of which have been documented returning back to private land (ibid). These male movements onto public lands are not considered relevant from a population establishment standpoint and there is no evidence at this time that any re-introduced individual has permanently moved onto the Plumas National Forest (ibid). In April, 2011 a fisher den established by a released Sterling Tract female, was located on the Lassen National Forest (ibid). Due to reproduction occurring on the Sterling Tract private land, the Forest Service anticipates that additional females may likely den on the Lassen NF in the coming years. Remaining fisher releases for 2011-2012 (8 females, 4 males) will likely occur closer to the Plumas NF than previous releases. Therefore, it is likely that the PNF will also have residing fishers in the next coming years.

The 2004 SNFPA Record of Decision (USDA 2004b) identifies large trees, large snags, large down wood, and higher than average canopy closure as habitat attributes important to fisher. CWHR size classes 4M, 4D, 5M, 5D, and 6 are identified as being important to fisher. A vegetated understory and large woody debris appear important for their prey species. The fisher's preferred forest types include montane hardwood conifer, mixed conifer, montane riparian, ponderosa pine, lodgepole pine, eastside pine, and possibly red fir. The higher-elevation forests are less suitable for fishers because of deep snow packs (USDI 2004). Table 55 displays the acres of denning (CWHR size-density classes 4D and 5D) and foraging (CWHR size-density classes 4M and 5M) habitat present in the wildlife analysis area.

Table 55. Suitable Pacific Fischer Habitat in the Wildlife Analysis Area (NFS Lands)

Habitat Use	CWHR Type	National Forest System Acres
Denning	4D/5D	13,454
Foraging	4M/5M	27,916
Total		41,370

The physical structure of the forest and the prey associated with forest structures are thought to be the critical features that explain fisher habitat use. Powell (in USDI 2004) states that forest type is probably not as important to fishers as the vegetative and structural aspects, and fishers may select forests that have low and closed canopies. Numerous studies (as referenced in the 2004 SNFPA Final Supplemental EIS) indicate that canopy closure over 60 percent is important, and fisher preferentially select home ranges to include high proportions of dense forested habitat. Stands with greater canopy cover, greater variation in tree size, and more hardwood and large snag components provide suitable resting habitat where fishers seek refuge during periodic resting bouts (Zielinski et al. 2010). The fisher's need for overhead cover was well documented in the April 8, 2004, Federal Register. Fishers select stands with continuous canopy cover to provide security cover from predators. The dense canopy increases snow interception, lowers the energetic costs of traveling between foraging sites, and preferred prey species may be more abundant and vulnerable in areas of higher canopy closure (ibid). A number of studies have shown that the fisher avoids areas with little forest cover or significant human disturbance and prefers large areas of contiguous interior forest (ibid.).

American Marten—In the Sierra Nevada, marten are most often found above 7,200 feet, but the species' core elevation range is from 5,500 to 10,000 feet (USDA 2001a). Recent studies (Zielinski 2004, Zielinski et al. 2005), which compared historical and contemporary records of martens, strongly indicates that populations now appear to be discontinuous in the northern Sierra Nevada. This reduction in their distribution is likely the result of several factors, including timber harvest on NFS lands, road building, and trapping.

There are over 40 records of marten observations/detections on the Plumas National Forest dating back to 1975. Only one record, a sighting in 1980 at Taylor Lake, is within close proximity to the wildlife analysis area. Extensive surveys using both soot-covered track plates and baited photo stations have been conducted since the mid-1990s across the majority of the Mt. Hough Ranger District landscape; no marten have been found (documented survey results are on file). Marten have not been detected during surveys conducted within and adjacent to the Keddie Ridge Project area; therefore, it is suspected that marten are likely not present in the wildlife analysis area.

Martens prefer coniferous forest habitat with large-diameter trees and snags, large down logs, moderate-to-high canopy closure, and interspersion of riparian areas and meadows (USDA 2001a). Martens generally avoid habitats that lack overhead cover; rather, they select stands with greater than 40 percent canopy closure for both resting and foraging and usually avoid stands with less than 30 percent canopy closure (ibid.). Foraging areas are generally in close proximity to both dense riparian corridors (used as travel ways) and forest meadow edges and include an interspersion of small (less than 1 acre) openings with good ground cover used for foraging (USDA 2001a).

Important forest types include mature mesic (moderately moist) forests of red fir, Sierra mixed conifer-fir, lodgepole pine, and eastside pine (USDA 2001a). The CWHR size-density classes 4M, 4D, 5M, 5D, and 6 are identified as moderately to highly important for the marten (ibid.). The red fir zone forms the core of marten occurrence in the Sierra Nevada (ibid.). Table 56 displays the acres of denning (4D, 5D) and foraging (4M, 5M) habitat present in the wildlife analysis area.

Table 56. Suitable Marten Habitat in the Wildlife Analysis Area (NFS Lands)

Habitat Use	CWHR Type	National Forest System Acres in Wildlife Analysis Area
Denning	4D/5D	12,389
Foraging	4M/5M	24,872
Total		37,261

Mountain Yellow-legged Frog

The only detections to date of mountain yellow-legged frogs (MYLFs) in the project area occurred in 1979, when four incidental sightings were reported. These sightings were on private land in the north arm of Indian Valley, two within Cooks Creek and two within Lights Creek. Formal amphibian surveys were conducted in the Keddie Ridge Project area in 2006 (Arroyo_Chico_Resources 2006). Contractors followed "A Standard Protocol for Surveying Aquatic Amphibians" (Fellers and Freel 1995). There were no detections of MYLFs during this survey. Many of the streams in the 2006 survey consisted of a cobble substrate and appeared to be highly suitable for MYLFs. However, large numbers of fish, primarily rainbow trout, were also detected in these streams. The presence of such fish populations lowers the suitability of streams for MYLFs (Arroyo_Chico_Resources 2006).

USDA Forest Service R5 Management Indicator Species

MIS for the PNF are identified in the 2007 Sierra Nevada Forests Management Indicator Species (SNF MIS) Amendment (USDA 2007e). The habitats and ecosystem components and associated MIS analyzed for the project were selected from this list of MIS, as indicated in Table 57. In addition to identifying the habitat or ecosystem components (1st column), the CWHR type(s) defining each habitat/ecosystem component (2nd column), and the associated MIS (3rd column), Table 57 discloses whether or not habitat for each MIS is potentially affected by the Keddie Ridge Project (4th column).

Table 57. Selection of MIS for Project-Level Habitat Analysis for the Keddie Ridge Project

Habitat or Ecosystem Component	CWHR Type(s) defining the habitat or ecosystem component[1]	Sierra Nevada Forests Management Indicator Species *Scientific Name*	Category for Project Analysis [2]
Riverine & Lacustrine	lacustrine (LAC) and riverine (RIV)	aquatic macroinvertebrates	3
Shrubland (west-slope chaparral types)	montane chaparral (MCP), mixed chaparral (MCH), chamise-redshank chaparral (CRC)	fox sparrow *Passerella iliaca*	3
Oak-associated Hardwoods & Hardwood/conifers	montane hardwood (MHW), montane hardwood-conifer (MHC)	mule deer *Odocoileus hemionus*	3
Riparian	montane riparian (MRI), valley foothill riparian (VRI)	yellow warbler *Dendroica petechia*	3
Wet Meadow	Wet meadow (WTM), freshwater emergent wetland (FEW)	Pacific tree frog *Pseudacris regilla*	2
Early Seral Coniferous	ponderosa pine (PPN), Sierran mixed conifer (SMC), white fir (WFR), red fir (RFR), eastside pine (EPN), tree sizes 1, 2, and 3, all canopy closures	mountain quail *Oreortyx pictus*	3
Mid Seral Coniferous	ponderosa pine (PPN), Sierran mixed conifer (SMC), white fir (WFR), red fir (RFR), eastside pine (EPN), tree size 4, all canopy closures	mountain quail *Oreortyx pictus*	3
Late Seral Open Canopy Coniferous	ponderosa pine (PPN), Sierran mixed conifer (SMC), white fir (WFR), red fir (RFR), eastside pine (EPN), tree size 5, canopy closures S and P	sooty (blue) grouse *Dendragapus obscurus*	3
Late Seral Closed Canopy Coniferous	ponderosa pine (PPN), Sierran mixed conifer (SMC), white fir (WFR), red fir (RFR), tree size 5 (canopy closures M and D), and tree size 6.	California spotted owl *Strix occidentalis occidentalis*	3
		northern flying squirrel *Glaucomys sabrinus*	3
Snags in Green Forest	Medium and large snags in green forest	hairy woodpecker *Picoides villosus*	3
Snags in Burned Forest	Medium and large snags in burned forest (stand-replacing fire)	black-backed woodpecker *Picoides arcticus*	2

[1] All CWHR size classes and canopy closures are included unless otherwise specified; Canopy Closure classifications: S=Sparse Cover (10-24% canopy closure); P= Open cover (25-39% canopy closure); M= Moderate

cover (40-59% canopy closure); D= Dense cover (60-100% canopy closure); Tree size classes: 1 (Seedling)(<1" DBH); 2 (Sapling)(1"-5.9" DBH); 3 (Pole)(6"-10.9" DBH); 4 (Small tree)(11"-23.9" DBH); 5 (Medium/Large tree)(≥24" DBH); 6 (Multi-layered Tree) [In PPN and SMC]

[2] Category 1: MIS whose habitat is not in or adjacent to the analysis area and would not be affected by the project.
Category 2: MIS whose habitat is in or adjacent to analysis area, but would not be either directly or indirectly affected by the project.
Category 3: MIS whose habitat would be either directly or indirectly affected by the project.

The two MIS included in this final EIS is the hairy woodpecker, due to the proposal to treat forested stands with medium to large snags, which is the habitat component for this MIS, and aquatic macroinvertebrates, due to the cumulative effects to watersheds. A summary of existing conditions and environmental effects for these two species, derived from the project level MIS Report, is presented in this final EIS. Affected environment and environmental consequences to the California spotted owl, also a MIS, can be found in the Forest Service R5 Sensitive Species sections of this final EIS. It has been determined that the habitat for the remaining MIS in Table 57, with the exception of two (wet meadows and snags in burned forest), will also be affected by this project but these effects are considered indirect, minor, or beneficial. Refer to the Keddie Ridge Project MIS Report for complete discussion of potential effects on all PNF MIS species due to implementation of this project.

Hairy Woodpecker

The hairy woodpecker was selected as the MIS for the ecosystem component of snags in green forests. Medium (diameter breast height between 15 to 30 inches) and large (diameter breast height greater than 30 inches) snags are most important. The hairy woodpecker uses stands of large, mature trees and snags of sparse to intermediate density; cover is also provided by tree cavities (CDFG 2006). Mature timber and dead snags or trees of moderate to large size are apparently more important than tree species (Siegel and DeSante 1999). Based on data derived from common stand exam plots within the Keddie Ridge Project, snags over 15 inches DBH, on average, exist at 3 snags per acre.

Aquatic Macroinvertebrates

Aquatic macroinvetebrates are MIS for riverine and lacustrine habitat in the Sierra Nevada. They have been demonstrated to be very useful as indicators of water quality and aquatic habitat condition (Resh and Price 1984, Karr et al. 1986, Hughes and Larsen 1988, Resh and Rosenberg 1989). They are sensitive to changes in water chemistry, temperature, and physical habitat; factors of particular importance are: flow, sedimentation, and water surface shade.

Aquatic macroinvertebrates are invertebrates that live in water and can be seen by the unaided human eye. They provide an important ecological link between microscopic food organisms and fish. Aquatic macroinvertebrates include insects, such as the commonly thought of mayflies, stoneflies, caddisflies, helgrammites and midges. Many of these groups are most highly developed for running water environments with adults and larvae living primarily in cold, running streams; many feed and breed under rocks, in the spaces among loose gravel and rocks, piles of waterlogged leaves and debris, and submerged logs.

There are nearly 1,000 miles of streams in the watershed analysis area. Approximately 53 percent of the stream miles are ephemeral, 32 percent are intermittent, and 15 percent are perennial. Ephemeral and intermittent streams are seasonal—they run water during some portion of the year, but are typically dry by late summer. Ephemeral streams only flow in response to storm events or snowmelt, and do not necessarily flow every year. Intermittent streams are seasonally connected to the surrounding water table and may flow during all but the driest months, whereas perennial streams typically flow year round.

Watershed sensitivity analyses for the HFQLG Pilot Project watersheds were reported in the HFQLG Forest Recovery Act Final Environmental Impact Statement (USDA 1999a). The sensitivity ratings were based on the erosion potential, slope steepness, amount of alluvial channels, risk of rain-on-snow and/or thunderstorm events, and on revegetation potential. The HFQLG Pilot Project watersheds applicable to this project received moderate sensitivity ratings. Based on these ratings, most subwatersheds analyzed in this assessment were considered to have moderate sensitivity and were assigned a “threshold of concern” (TOC) value of 12 percent of the subwatershed area refer to the MYLF cumulative effects section below for further discussion of TOC).

Migratory Landbirds

Under the National Forest Management Act (NFMA), the Forest Service is directed to “provide for diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives.” (P.L. 94-588, Sec 6 (g) (3) (B)). The January 2000 USDA Forest Service Landbird Conservation Strategic Plan (USDA 2000a) followed by Executive Order 13186 in 2001, in addition to the Partners in Flight (PIF) specific habitat Conservation Plans for birds and the January 2004 PIF North American Landbird Conservation Plan reference goals and objectives for integrating bird conservation into forest management and planning.

The Plumas National Forest utilizes the U.S. Fish and Wildlife Service 2008 Birds of Conservation Concern for the Sierra Nevada as its framework for analyzing effects to migratory birds. Of this list of eleven birds, Keddie Ridge project level reports (e.g. BA/BE, MIS) address nine of the species either directly or by using a surrogate species that utilize the same or similar habitat attributes. Table 58 highlights how and where these nine migratory birds are addressed directly or by using a surrogate species.

Table 58. Analysis of Migratory Birds for the Keddie Ridge Project

Birds of Conservation Concern (Sierra Nevada - BCR 15)	Forest Service Sensitive Species (S) or Management Indicator Species (MIS)	Project Level Report (BA/BE or MIS)	Critical Habitat component or threat as defined by Sierra Nevada Bird Conservation Plan (PIF)
Bald Eagle	Bald Eagle (S)	BA/BE	Designated as a non-land bird by DeSante
Flammulated Owl	Mule Deer (MIS) Hairy Woodpecker (MIS)	MIS MIS	Depends critically on oaks or oak woodlands, Loss of snags
California Spotted Owl	California Spotted Owl (S)	BA/BE	Depends critically on old growth
Calliope Hummingbird	Sooty (Blue) Grouse (MIS) Yellow Warbler (MIS) Willow Flycatcher (S)	MIS MIS BA/BE	Open Forested habitats, and moist habitats on the East Slope
Lewis' Woodpecker	Hairy Woodpecker (MIS)	MIS	Loss of snags
Williamson's Sapsucker	Hairy Woodpecker (MIS)	MIS	Loss of snags
Olive-sided Flycatcher	California Spotted Owl (S) Hairy Woodpecker (MIS)	BA/BE MIS	Utilize late successional/old growth forest, but does not depend on it critically, Loss of snags
Willow Flycatcher	Willow Flycatcher (S)	BA/BE	Depends critically on montane meadow habitat
Cassin's Finch	California Spotted Owl (S)	BA/BE	Depends critically on old growth

The remaining two species, the Peregrine Falcon and Black Swift, occur in known established sites or have habitats that are very localized and limited in extent on the Plumas NF.

Peregrine Falcon

PNF biologists have reviewed habitat for the Peregrine Falcon on the Plumas NF extensively since the early 1980's. Documented eyries for the Peregrine falcon consists of three rock cliff sites on the Forest, located at Bald Rock (Feather River RD), Pulga (Feather River RD), and North Fork of the Feather River (Mt. Hough RD), just west of Canyon Dam. Disturbance to these habitats is limited, as most activities do not impact these rock cliff sites. Projects that falls within a ½ mile vicinity of these three sites would analyze impacts to Peregrine Falcon, whereas projects outside of a ½ mile vicinity of these sites would not require further analysis. The Canyon Dam site is located over two miles to the west of proposed Keddie Ridge Project activities. No direct or indirect effects are expected to occur to this territory with implementation of the Keddie Ridge Project and consequently does not require further analysis.

Black Swift

Based on surveys and work by the Plumas County Audubon Society the Black Swift is a rare spring and fall migrant across the PNF and has not been confirmed as a resident on the PNF. However suitable wet cliff/waterfall habitat does occur at selected sites on the Forest. Two sites appear to be suitable for Black Swifts, Feather Falls on the Feather River RD and Frazier Falls on the Beckwourth RD. Both sites fall within recreation areas or recreation sites, and do not receive ground disturbing activities that would modify or alter habitat values for the Black Swift. No known sites occur in or are within a ½ mile of the Keddie Ridge Project area.

Environmental Consequences

Summary of Effects

The Keddie Ridge Project Wildlife Biological Assessment / Biological Evaluation (USDA 2011b) provides a discussion of the direct, indirect, and cumulative effects for all sensitive animal species analyzed for the Keddie Ridge Project. The BA/BE is located in the Keddie Ridge Project record and incorporated by reference. The BA/BE concluded that the Keddie Ridge Project would not affect the following species: California red-legged frog, Foothill yellow-legged frog, Valley elderberry longhorn beetle, northern leopard frog, greater sandhill crane, and Swainson's hawk.

Based on the direct, indirect, and cumulative effects discussed in the BA/BE, it was concluded that the Keddie Ridge Project would affect individuals but would likely not result in a trend toward listing or loss of viability for the following species: hardhead minnow, mountain yellow-legged frog, northwestern pond turtle, Sierra Nevada red fox, pallid bat, Townsend's big eared bat, western red bat, willow flycatcher, bald eagle, California spotted owl, northern goshawk, great gray owl, California wolverine, American marten, and Pacific fisher.

The NEPA (*National Environmental Policy Act*) process requires agencies to identify "the significant environmental issues deserving study and de-emphasizing insignificant issues, narrowing the scope of the environmental impact statement" 40 CFR 15001.1(d). Due to the high visibility of old-forest species in California, and the potential impacts of fuels treatment, group selection, and area thinning on forested habitat, the effects on bald eagle, California spotted owl, northern goshawk, American marten, and Pacific fisher are emphasized in this EIS. The mountain yellow-legged frog is also emphasized in this Final EIS due to the proposed use of herbicides in riparian habitat conservation areas (RHCAs) and proposed DFPZ and area thinning within RHCAs.

Terrestrial Wildlife Species

All Action Alternatives (A, C, D, and E)

DFPZ and area thinning treatments applied to CWHR size-density class 4M and 4D stands, which provide important foraging, nesting, and denning habitat to old-forest species, would modify stand structure attributes, species composition, and landscape structure (distribution of CWHR size class and density and percent of open canopy forest conditions created). Based on silviculture prescriptions and design criteria specific to the Keddie Ridge Project, it is expected that the majority of size-density 4M and 4D stands treated under all alternatives would retain habitat suitability values for old-forest species. Alternative D would have the least adverse effects on habitat suitability, reducing 553 acres of 4D stands to a 4M condition. No stands under this alternative would be reduced to an unsuitable state (4P or below). Alternative C, the non-commercial alternative, would reduce the same amount of 4D stands as alternative D as well as create approximately 234 acres of 4P (unsuitable) due to thinning some 4M stands to below 40 percent canopy cover. Alternative C would maintain 92 percent of treated 4M and 4D stands in a suitable state. Alternatives A and E, with implementation of group selection and heavier DFPZ prescriptions, would have the largest adverse effects on habitat suitability but still maintain 66 percent and 57 percent, respectively, of treated 4M and 4D acres in a suitable state. Alternative A would reduce 1,052 acres to an unsuitable condition (818 acres to 4P, 234 acres to GS) and alternative E would reduce 1,325 acres to an unsuitable condition (1,082 acres to 4P, 243 acres to GS).

Approximately 1,303 acres of CWHR size density class 5M and 5D is proposed for treatment under each action alternative. These stands, with their larger tree components and higher canopy closure, provide important nesting habitat for spotted owls and goshawks and denning habitat for mesocarnivores. Approximately 140 acres of 5D under alternatives A, C, and E and 130 acres of 5D under alternative D would be reduced to a 5M condition. Unique prescriptions associated with each alternative more fully identifies the effects of treatments to 5M and 5D structural elements. Alternative E would result in the heaviest treatments, with up to 30 inch DBH trees removed while maintaining a 40 percent CC. Prescriptions under alternative A would adhere to an upper diameter limit of either 20 or 24 inch DBH trees and would maintain 40-50 percent CC. Alternative D prescribes removal of up to 20 inch trees, leaving 50 percent CC. Alternative C, the noncommercial alternative, would have the lightest treatment, thinning to 12 inch DBH and maintaining 40-50 percent CC in treated 5M and 5D stands.

The majority of group selection treatments proposed under alternatives A and E would be located outside of CWHR 5M and 5D stands (88 percent under alternative A, 81 percent under alternative E). However, a small percentage of GS acres would fall within size and density class 5M stands considered suitable for nesting owls. No 5D habitat is proposed for GS. GS units under alternative A would treat approximately 34 acres of 5M habitat. Alternative E would treat, thru GS, approximately 60 acres of 5M. These acres would exist in a Sierran mixed conifer (SMC 1) state after group selection treatment.

Table 59 shows the cumulative changes in CWHR size density classed 4M, 4D, 5M, and 5D that would occur from implementing the DFPZs, area thinning, and group selections proposed in the action alternatives.

Table 59. Approximate Change in CWHR Size Density Classes 4M, 4D, 5M, 5D Habitat Types in the Wildlife Analysis Area (Based on 66,040 National Forest System Acres)

CWHR Size Density Class	No Action Alternative (Existing Acres)	Alternative A Post-Project	Alternative C Post-Project	Alternative D Post-Project	Alternative E Post-Project
4M	18,865	18,384	19,184	19,418	18,111
	% remaining	97%	103%	103%	96%
4D	7,485	6,914	6,932	6,932	7,039
	% remaining	92%	93%	93%	94%
5M	9,051	9,157	9,191	9,182	9,129
	% remaining	101%	102%	101%	101%
5D	5,969	5,829	5,829	5,838	5,829
	% remaining	98%	98%	98%	98%
Total Change	41,370	40,284	41,138	41,370	40,108
		97%	100%	100%	97%

California Spotted Owl

Two PACs would be entered under all action alternatives to conduct low intensity underburns (PAC 84 – 65 acres, PAC 131 – 8.4 acres). The objectives of this treatment would be to reduce fuel loads and thus decrease potential effects of wildfire. No other activities are proposed in PACs or SOHAs.

Eight of the 15 HRCAs in the analysis area would be affected by proposed treatments under the action alternatives. Under alternatives A, C, and E, four HRCAs would see a reduction in suitable acres. The percent reduction in these four HRCAs would range from 1 percent to 16 percent and would include some group selection acreage. Group selection under alternative E is estimated to reduce a small percentage of nesting habitat in two HRCAs (PL165 – 2 acres of Sierra Mixed Conifer (SMC) 5M, PL254 – 23 acres of SMC 5M).

Northern Goshawk

Fuel treatments, group selections, or area thinning proposed in the action alternatives would not occur in any of the eight northern goshawk PACs present in the wildlife analysis area.

Mesocarnivores (American marten and Pacific Fisher)

No direct effects to mesocarnivores are expected due to the likelihood of no individuals inhabiting the wildlife analysis area.

Alternatives A and E, due to the heavier DFPZ treatments and group selections proposed, would reduce some mesocarnivore suitable habitat to an unsuitable state (CWHR 4P or SMC 1). Reductions in denning habitat would occur under all alternatives as a result of thinning treatments opening up the canopy closure. Denning habitat treated under alternatives A and E would be reduced by 4.6 percent and 5.3 percent respectively. Alternatives C and D would reduce denning habitat by 5 percent. Suitable foraging habitat treated under alternatives A and E would result in a decrease of 1.3 percent and 2.4

percent respectively. Alternatives C and D, due to the reduction of 5D and 4D stands to an M state as a result of thinning, would increase existing foraging acres by 450 and 693 acres respectively.

Alternative B (No Action)

Alternative B would pose no risk and uncertainty associated with the proposed actions, but it would maintain a high risk of potential habitat loss from wildfire, while the action alternatives would reduce this risk.

Aquatic Wildlife Species

All Action Alternatives (A, C, D, and E)

Approximately 1,279 acres of riparian habitat conservation areas (RHCAs) would be entered for treatment under each action alternative. All alternatives would apply specific RHCA prescriptions that would maintain suitable habitat values for aquatic species and meet riparian management objectives (RMOs) while creating riparian conditions that would be less susceptible to high-severity fire. This reduction of long-term threat of stand-replacing fire as a result of treatments would offset any short-term minor effects.

The Keddie Ridge Project cumulative watershed effects analysis concluded that, following implementation of any of the action alternatives, no subwatersheds would be at or exceed the threshold of concern (TOC). Thus, suitable riparian conditions for aquatic species would not be susceptible to significant adverse cumulative effects as a result of fuel reduction activities implemented under the Keddie Ridge Project.

Based on the latest risk assessments and application design criteria, the herbicides proposed under alternatives A and E to control noxious weeds would pose no significant adverse effects to wildlife species.

Mountain Yellow-legged Frog

Potential direct effects are expected to be negligible to MYLFs due to the likelihood, based on survey results, that populations are not present in treatment areas.

Suitable MYLF riparian habitat would be affected under all alternatives but, based on RHCA prescriptions and design criteria (including equipment exclusion zones), implementation of best management practices, and implementation of soil and water standards (RMOs), adverse effects would be minimal.

Alternative B (No Action)

Alternative A would pose no risk and uncertainty associated with the proposed actions, but it would maintain a high risk of potential habitat loss from wildfire. The action alternatives would reduce this risk. There would be no direct effects on aquatic wildlife species because no activities would occur to create disturbance or result in any impacts on the existing habitat conditions.

Environmental Consequences: USDA Forest Service R5 Sensitive Species

Bald Eagle

All Action Alternatives (A, C, D, and E)

Direct Effects

Area thinning is proposed on approximately 46 acres in the primary nest zone of the Round Valley bald eagle territory. These treatments would occur in two units of the Keddie Ridge Project, units 75 and 75a. Unit 75 comprises 34 acres and is located on the north side of NFS road 26N19, approximately 0.12 miles (800 feet) from the active nest tree. Area thinning treatments in Unit 75 would take place in 19 acres typed as CHWR Sierra Mixed Confer (SMC) 5D and 15 acres typed as SMC 5M. The prescriptions for each action alternative in unit 75 would be as follows: alternative A—thin to 40 percent canopy closure (CC) and up to 24 inch DBH trees; alternative C—thin to 40-50 percent CC and up to 12 inch DBH trees; alternative D—thin to 50 percent CC and up to 20 inch DBH trees, leave 25 percent of stand untreated; alternative E—thin to 40-50 percent and up to 30 inch DBH trees. Unit 75a comprises 12 acres of SMC 5M and is located south of NFS road 26N19 and is adjacent to unit 75. The active nest tree is located in the very southwest corner of this unit, immediately adjacent to private property. The treatment prescriptions for unit 75a under all action alternatives are the same—hand thin, pile, and burn trees less than 8 inch DBH trees. Light underburning treatments are also proposed within both units.

A short temporary road (approximately 200 feet) would be constructed off of FS road 26N19 to access unit 75. At the end of this temporary road a landing would be constructed to receive and facilitate removal of forest products from the 34 acres to be treated. This landing would potentially be ½ acre in size and all existing trees would require removal. The temporary road would be decommissioned upon project completion.

Area thinning prescriptions are designed to accelerate stand growth and provide for future CWHR size class 4 and 5 trees. Area thinning prescriptions are also designed to encourage long-term regeneration of large pines by maintaining the largest and most fire-resilient dominant and codominant trees. The resulting stand condition of such thinning would be an uneven-age forest structure composed of ponderosa and sugar pine greater than 38 inches DBH with total canopy cover of 40-50 percent. Protection and enhancement of nesting habitat by thinning smaller conifers would improve the growth of the residual ponderosa and sugar pines, while surface and ladder fuel reduction would protect the larger tree component for future nest trees. Therefore, the area thinning treatments implemented under the action alternatives would be deemed a beneficial effect, resulting in additional suitable nesting habitat for bald eagles in the future.

The hand thin, pile, and burn treatments proposed in the nest stand unit (unit 75a) would limit the opening of this stand but still remove small diameter (less than 8 inch) trees, which comprise the majority of the ladder fuels. This would result in improved stand conditions by reducing potential wildfire effects while still concealing the nest tree from NFS road 26N19.

Indirect Effects

Changes in the fishery production are not expected in Round Valley Reservoir as a result of implementing proposed DFPZ and area thinning treatments immediately adjacent to the reservoir. Implementing best management practices and meeting all riparian management objectives (the RMO analysis is located in the “Hydrology and Soils” section of this chapter) would ensure that there would be no indirect effects on the fishery or fishery habitat.

To limit disturbance to nesting eagles, the following standard management requirements would be followed: a Limited Operating Period (LOP) would be implemented not allowing area thinning treatments in the Round Valley bald eagle territory (units 75 and 75a) between January 1 and August 15 along NFS road 26N19. No log haul is to occur on this road during the LOP.

Cumulative Effects

The parcels of private ownership land in the Bellas Flat area surround the existing nest tree. The nest tree is on national Forest System land but is 30 feet from the private property. The old growth timber which once existed on the private land within ½ mile of the nest has been heavily cut, with no potential nest trees remaining. Approximately 60 percent of the nest site area and 80 percent of the primary use area are privately owned (as identified in the Round Valley Bald Eagle Management Plan, November 1989). There is continuous pressure to initiate logging activities on private land around the nest that could be adverse to nesting activity.

NFS road 26N19 runs through both the primary nest site area and the secondary nesting area of the Round Valley territory. The existing condition of this road is such that use is limited during the critical stages of nesting because of snow, mud, large dips full of water, and generally poor conditions for vehicle use. No evidence exists that past and present recreational and general use of this road has caused adverse impacts to eagle production/nesting. However, it is a concern that any future road improvements to this road could lead to increased use, which could adversely affect eagle nesting. To remove forest products from unit 75, as proposed under the action alternatives, a small southern section (approximately 120 yards) of NFS road 26N19 could receive minor improvements. The limiting sections of this road to vehicle traffic (due to poor surface conditions) exist north of this short haul route. Therefore, any improvements to NFS road 26N19 associated with implementation of the Keddie Ridge Project is not expected to lead to increased use.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the bald eagle.

Alternative B (No Action)

Direct Effects

There would be no direct effects on the bald eagle or existing bald eagle habitat. No activities would occur that would cause disturbance to nesting, wintering, or migrating birds.

Indirect Effects

The indirect effects of no action would include the potential for future wildfire and related impacts on habitat development and recovery. The silvicultural recommendations for habitat management presented in the Round Valley Bald Eagle Management Plan to promote present and future bald eagle nesting and foraging activities within the Round Valley Bald Eagle Management Area (BEMA) would not occur. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and could create a more severe burn. Increased rates of spread would result in potential loss of bald eagle nesting habitat and other important habitat attributes such as large trees and snags.

Cumulative Effects

No acres of suitable habitat would be treated and would not reduce the average suitability of any habitat types within the analysis area for bald eagles.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the bald eagle.

California Spotted Owl

All Action Alternatives (A, C, D, and E)

Direct Effects

The analysis of direct effects on California spotted owl (CSO) is focused on PACs and spotted owl Habitat Areas (SOHAs) existing or created as a result of surveys. The effects on other potentially suitable nesting and foraging habitat outside of PACs are discussed in the "Indirect Effects" section below. Direct effects are expected to be minimal for all action alternatives, as described below.

Direct effects on spotted owls are anticipated within two PACs—PL084 and PL131. The remaining 14 PACs within the analysis area would not be entered for treatment under this project. A low intensity underburn on 65 acres in PL084 and 8.4 acres in PL131 is proposed under all action alternatives. The same underburn prescription is proposed in 105.5 acres of SOHA R3, which is associated with PL084. This prescription will result in less than 10 percent mortality n dominant and codominant trees and CWHR suitability on treated acres will remain unchanged. To prevent disturbance to potential nesting birds, underburning activities within PACs and SOHA would take place outside of the nesting season (appendix H).

If spotted owls are detected during future surveys or project-related activities, PACs and home range core areas (HRCAs) would be delineated, and all treatments would be modified to comply with the standards and guidelines in the HFQLG Act final EIS and Record of Decision (USDA 1999a, b) and the SNFPA 2004 ROD (USDA 2004b).

Limited Operating Periods (LOPs) would be implemented within 0.25 mile of treatment units for active nests identified during present and future surveys or incidental detections. An LOP would also be applied to haul routes within 0.25 mile of an active nest. LOPs are expected to reduce impacts from increased human activity and vehicle and equipment noise. Disturbance would be limited to individual treatment units and would last a few days to two weeks in any location. Impacts from disturbance are not expected to substantially affect habitat use or reproductive capacity of this species.

No new road construction would occur in spotted owl PACs or SOHAs. A LOP could be applied for any road reconstruction in PACs.

Proposed treatment activities could occur as early as fall 2011 and may continue five years beyond the initiation of implementation. There is the potential that spotted owls could establish new, undocumented territories (activity centers) during project implementation and would not be protected as PACs. The decision to conduct additional protocol surveys within the project area will be made by the district biologist based on project implementation timelines.

Indirect Effects

Based on the vegetation map and CWHR model, about 15,020 acres of National Forest System lands in the wildlife analysis area may be considered suitable spotted owl nesting habitat (CWHR size/density classes 5M and 5D), and about 26,350 of National Forest System acres may be considered suitable foraging habitat (CWHR size classes 4M and 4D) (Table 53). The total acres of suitable owl habitat in the wildlife analysis area that would remain after implementation of each action alternative is presented in Table 59 above. The post-project CWHR changes summarized in Table 59 are based on the silviculture prescription assigned to each CWHR stand within treatment units (refer to chapter 2 for prescription details for each alternative). Prescriptions are unique and the variables that change are canopy closure and general retention size for trees.

Changes to suitable spotted owl foraging habitat (CWHR size classes 4M and 4D) as a result of implementing project activities would occur under all action alternatives. Approximately 3,065 acres of 4M and 4D habitat is proposed for treatment under each alternative. Prescriptions that would result in 4M and 4D stands reduced to an unsuitable state (4P or SMC 1) fall within some DFPZ units and all group selection (GS) units in Alternatives A and E. Alternative A would reduce 818 acres of 4M/4D stands to a 4P state (256 acres from 4D, 562 acres from 4M). Group selection treatments under alternative A would reduce an additional 234 acres of 4M and 4D stands to a SMC 1 condition (approximately 82 acres from 4D and 152 acres from 4M). Alternative E would reduce 1,082 4M/4D acres to a 4P state (361 acres from 4D, 721 acres from 4M). Group selection treatments under alternative E would reduce an additional 243 acres of 4M and 4D stands to an SMC 1 condition (approximately 85 acres from 4D and 158 acres from 4M). GS treatments would specifically target areas dominated by uniformly sized, smaller white fir and that have significant amounts of small down logs or standing small deadwood. Alternatives C would reduce approximately 234 acres of 4M to a 4P state thru thinning 12 inch DBH or smaller trees and creating open (below 40 percent) canopy cover conditions. No stand treated under alternative D would be reduced to an unsuitable state.

The amount of 4D stands reduced to a 4M condition (i.e. canopy closure after treatment would be 40-60 percent) under each alternative would be as follows—alternative A-233 acres, alternatives C and D-553 acres, and alternative E-125 acres. Although canopy cover down to 40 percent is considered suitable for foraging (USFWS 2005), it appears to be only marginally so based on owl occurrence and productivity threshold at around 50 percent canopy cover (Verner et al. 1992). Under all alternatives, the majority of DFPZ and area thinning treatments applied to CWHR 4M and 4D stands would result in no change to CWHR size class or canopy closure class. Of the approximate 3,065 acres of 4M and 4D habitat proposed for treatment, (92 and 100 percent) under alternatives C and D, respectively, would continue to provide suitable foraging conditions for the spotted owl. No group selection would occur under these two alternatives and treatments such as light thinning, mastication, hand-thinning, underburning would maintain these stands in a suitable CWHR state. Alternatives A and E, which would implement group selection and heavier DFPZ treatments, would maintain 2,013 acres (66 percent) and 1,740 acres (57 percent), respectively, of treated 4M and 4D acres in a suitable state.

Based on recent habitat assessments of 103 CSO territorial sites across the Plumas Lassen study area (Keane 2010) the habitat value to nesting/roosting spotted owls of size class 4 stands with a moderate canopy cover increases significantly when larger tree (LT) components (i.e. contribution of greater than 24 inch trees to the total tree crown cover) were recorded. Based on stand exam data collected and modeled for the Keddie Ridge Project, this large tree component exists in a majority of the post-project 4D and 4M stands (i.e. large tree attributed recorded in approximately 55 percent of stands). These areas, based on recent research findings (ibid), would likely provide not just foraging conditions for the spotted owl but also suitable nesting/roosting conditions.

Suitable nesting habitat (CWHR 5M and 5D) proposed for treatment under all alternatives, with the exception of group selection units, is expected to remain suitable for spotted owls (i.e., no change or reduced to 5M). Approximately 1,303 acres of 5M and 5D is proposed for treatment under each action alternative. Mechanical thinning in 140 acres of 5D under alternatives A, C and E and 130 acres under alternative D would reduce these stands to a 5M condition. Unique prescriptions associated with each alternative more fully identify the effects of treatments to 5M and 5D structural elements. Alternative E would result in the heaviest treatments, with up to 30 inch DBH trees removed while maintaining a 40 percent CC. Prescriptions under alternative A would adhere to an upper diameter limit of either 20 inch or 24 inch DBH trees and would maintain a 40-50 percent CC. Alternative D prescribes removal of up to 20 inch trees, leaving 50 percent CC. Alternative C, the noncommercial alternative, would have the lightest treatment, thinning to 12 inch DBH and maintaining 40-50 percent CC in 5M and 5D stands.

The majority of group selection treatments proposed under alternatives A and E would be located outside of CWHR 5M and 5D stands (88 percent under alternative A, 81 percent under alternative E). However, a small percentage of GS acres would fall within size and density class 5M stands considered suitable for nesting owls. No 5D habitat is proposed for GS. GS units under alternative A would treat approximately 34 acres of 5M habitat. Alternative E would treat, thru GS, approximately 60 acres of 5M. All acreage treated with GS would be reduced to a SMC 1 condition, which is considered unsuitable for spotted owl nesting or foraging. GS treatments in all CWHR types would specifically target areas dominated by uniformly sized, smaller white fir and that have significant amounts of small down logs or standing small deadwood.

Group selection treatments, as proposed under alternatives A and E, would create early seral stages and would contribute to heterogeneous stand structures that may be more resilient to disturbance events (such as fire, drought, and insect and disease infestations) on the landscape scale. The treatment would not result in areas that prevent access to adjoining suitable habitat. By design, group selections make up approximately 11.4 percent of any given stand. The small size of the groups (0.5 acre to 2 acres) would not preclude owls from flying over or around the treated areas. While the implementation of the group selections may not result in fragmentation in the classic sense, they would reduce the value of the habitat within the stand and would likely cause changes in the behavioral use of the territory, particularly with respect to foraging. Allowance would be made to retain up to two of the largest snags per acre in group selection units, unless removal would be necessary for safety and operability. Based on past projects and discussions with Occupational Safety and Health Administration safety representatives, it is anticipated that the majority of snags would be felled, and very few snags would be left in the 284 acres of group selection under alternatives A and the 326 acres of group selection under alternative E.

Improving forest health is one of the objectives of the Keddie Ridge Project and this includes improving vigor of residual trees by reducing stand density and competition. An important design element common to all action alternatives that would help meet such objectives is biomass (less than or equal to 10-inch trees) removal in mechanical thin units. This size class in a stand provides complexity and structure, as well as the diverse microclimates that owls seek to control exposure and changes in ambient temperature for roosting. Biomass removal can degrade or remove hiding cover in the lower and mid canopy often used by young of the year owlets. On average, the following percentage of stand biomass would be retained in mechanical thin units: under alternatives A and E 27 to 30 percent in CWHR size class 4 and 17 to 22 percent in CWHR size class 5. Alternatives C and D would retain, on average, more biomass in these same units; 41 to 48 percent in CWHR size class 4 and 34 to 44 percent in CWHR size class 5.

Irwin and Rock (Irwin and Rock 2004) found that the probability of stand use by spotted owl increased strongly as basal area rose from 80 to 320 square feet per acre (optimum range is between 160 and 320 square feet per acre) and was positively influenced by the number of trees per acre that were greater than 26 inches DBH. With implementation of mechanical thinning under alternatives A and E the residual basal area in CWHR size class 4 would average 141 to 143 square feet per acre and 163 to 167 in CWHR size class 5. Under alternatives C and D, mechanical thin units in CWHR size class 4 would average 166 to 184 square feet per acre and CWHR size class 5 stands would average 196 to 201 square feet per acre.

Eight of the 15 HRCAs in the analysis area would be affected by proposed treatments under all alternatives (Table 60). Two alternatives, A and E, would decrease existing suitable acres in four HRCAs as a result of implementation of DFPZ and group selection (GS) treatments. Estimated HRCA GS would occur in 4M or 4D stands with the exception being alternative E, which would treat 2 acres of 5M in PL165 and 23 acres of 5M in PL254. Alternative C would decrease existing suitable foraging acres in two HRCAs as a result of thinning 12 inch DBH or below trees to an open cover (4P) condition. HRCA acres treated under alternative. HRCA acres treated under alternative D would retain sufficient size trees and canopy closure to result in no change to existing CWHR size and density classes. No group selection would occur under alternatives C and D.

Table 60. Summary of Existing Conditions and Treatment Effects to Spotted Owl HRCAs

HRCA	Total HRCA acres	Existing suitable acres	Total treated acres	Acres reduced to unsuitable (% reduction)			Estimated group select acres	
				Alt A	Alt C	Alt E	Alt A	Alt E
PL084	717	650 (91%)	27

PL283	726	664 (92%)	1					

Several studies provide insight into spatial availability of habitat for California spotted owls (Hunter et al. 1995, Bingham and Noon 1997, Meyer et al. 1998, Franklin et al. 2000, Blakesley 2003, Zabel et al. 2003). Blakesley (2003) states that occupancy, apparent survival, and nesting success all increased with increasing amounts of old-forest characteristics, and reproductive output decreased with increasing amount of nonhabitat within a 500 acre area surrounding nest sites. Blakesley's data indicates that 71 percent suitable habitat within this nest area should be a minimum management target (Blakesley 2005). These studies suggest that effects outside of the PAC (on another 200 acres) may influence a site's "quality" for spotted owls. Based on these studies, it could be assumed that management actions that reduce high-quality spotted owl habitat within a 500-acre area around known nests could present more risk to owls than activities occurring outside of this area.

Using GIS, a 500-acre nest core area for each spotted owl activity center was created. Existing suitable habitat was added to each circle, along with all proposed Keddie Ridge Project treatments. Of the sixteen 500-acre nest cores within the analysis area, only 5 have acreage that will be treated under each alternative. Table 61 (column 2) summarizes the existing condition within these five nest cores. PL241 is the only nest core affected that currently exists at 70 percent suitable habitat, which is just below the minimum management target of 71 percent stated by Blakesley (2005). The 28 acres in this nest core is proposed for hand thin, pile, and burn treatment, which will not reduce suitability in these acres. As Table 61 shows, the remaining four nest cores contain 80-100 percent suitable acres.

Table 59summarizes the effects to suitable CWHR 4M, 4D, 5M, and 5D within the five CSO territories that would be affected by treatments. Total proposed acres of treatment within each nest core is as follows: PL084—99 acres, PL130—16 acres, PL165—21 acres, PL170—38 acres, PL241—28 acres. Under alternative A, based on planned DFPZ treatments in CWHR 4M that would mechanically thin to 30-40 percent canopy closure, 13 acres within PL084 nest core and 2 acres within PL170 nest core would be reduced post-project to an unsuitable condition (CWHR 4P). Under alternative E, based on similar proposed fuel treatments that would remove trees up to 30 inches DBH and create more open canopy conditions unsuitable to the owl, acres in the following nest cores would be reduced to unsuitable : PL084—13 acres of 4M reduced to 4P, PL165—18 acres of 4D reduced to 4P, PL170—2 acres of 4M reduced to 4P. PL084 and PL165 nest cores include portions of two Keddie Ridge DFPZ units where group selection (GS) is proposed under alternatives A and E. The precise acreage and location of group selections in each of these units (42, 81) would be determined in the field b project foresters considering topography, vegetation type, and proximity of resources of concern. An estimated 1.5 acres of group selection in each of these two nest core areas could occur, resulting in additional unsuitable acres from those stated above and displayed in Table 61. Under alternatives A and E PL084 nest core could have 1.5 acres in CHWR 4M reduced by GS and PL165 nest core could have 1.5 acres in CWHR 4D reduced by GS. The percent reduction of suitable acres in these three nest cores is as follows: PL084 – 3 percent, PL165 (alternative E only) – 4.3 percent, PL170 – less than 1 percent.

Table 61. Summary of Existing Condition of 500-Acre Nest Cores Affected by Proposed DFPZ and Area Thinning Treatments and Project's Effects to Suitable CWHR

PAC	Existing suitable nest core acres	Effects to CWHR size/density	Treated acres			Proposed treatment prescription*			
			Alt A	Alt C/E	Alt D	Alt A	Alt C	Alt D	Alt E
PL 084	425 (80%)	4M → 4P	13	13	0	Rx4	Rx8	no acres	Rx13
		4M unchanged	78	78	92	low to moderate underburn			
		4D unchanged	7	7	7	low to moderate underburn

*Rx2: Thin to 30-40% CC, 30" UDL , Rx3: Thin to 40% CC, 24"UDL, Rx4: Thin to 30-40% CC, 24" UDL, Rx8: Thin to 12" UDL 30-50% CC, Rx9:Thin to 20" UDL, 50% CC, Leave 15% of the stand untreated, Rx13: Thin to 30-40% CC, 30" UDL

DFPZ, area thinning, and group selection treatments under all alternatives would not reduce CWHR 5M and 5D to an unsuitable state. The only CWHR size class 5 in the affected nest cores is 7 acres of 5M in PL170. Under all action alternatives, these acres are proposed for mastication treatment of trees less than 10 inches DBH, resulting in no change to CWHR.

By quantifying the habitat changes within the home range as a result of project actions, a risk assessment based on habitat needs as outlined by Verner et al. (1992) and Blakesley (2003) among others, can be completed. This method or derivatives of this method have been used for over a decade to predict potential effects and the subsequent risk of implementing vegetation management projects. While there is a large amount of data on habitat suitability with regard to spotted owls, there have been no comprehensive studies on the impacts of vegetation management activities on reproductive success, impacts to prey, and long-term viability at the landscape level within a managed landscape. Specifically, although a risk assessment can be made when projects reduce habitat within a territory below a given threshold, no data exists that permit a reasoned prediction of impacts that vegetation management activities may have when the amount of suitable habitat remains above a given threshold.

The size of the home range selected for this analysis is reflective of breeding home range sizes elsewhere in the Sierra bioregion for mixed conifer forests. While a specific home range size is not discussed per se within the 2004 Record of Decision on the SNFPA Final Supplemental EIS, the Record of Decision does reference an analysis-size circle of 1.5 miles in diameter around the activity center, which equates to approximately 4,500 acres. Home range sizes for the California spotted owl are reported to vary between 3,000 acres (Call et al. 1992, Verner et al. 1992)for breeding pairs to as much as 12,500 acres (Verner et al. 1992) for non-breeding pairs on the east slopes of the Cascade Range. This analysis uses findings from Verner et al. (1992) and SNFPA guidelines (USDA 2004b) in delineating spotted owl home ranges as a circle of approximately 4,500 acres (1.5 mile radius) surrounding the territorial site.

Table 62 shows the amount of suitable habitat and effects of treatment in each territorial home range potentially affected by the Keddie Ridge Project. Thirteen 1.5 mile radius home ranges would have acres treated under this project. Following implementation, all but two (PL102 and PL254) would contain above 30 percent suitable habitat within the 4,500-acre home range, which is the minimum threshold recommended by Bart (1995). The pre-existing suitable home range condition for PL102 is 26 percent and for PL254 it is 20 percent. DFPZ and group selection treatments under alternatives A and E within these two home ranges would change 3 percent of acres in PL102 and 1 percent-10 percent of acres in PL254 to an unsuitable state. Overall, the remaining suitable spotted owl habitat home range percentage for these two territories would only be reduced by 1-2 percent over pre-project levels. The vegetation map used for this analysis indicates these two home ranges include a significant amount of private forested land, which may provide additional suitable acres (as much as 61 percent more for PL102 and 48 percent more for PL254). The home range for PL165 would exist post-project at close to the 30 percent threshold. A large portion of this territory also falls on private forested land, which may provide additional suitable acres (+32 percent).The average percent reduction in suitable habitat for all 4500-acre home ranges is 3 percent for alternative A and 6 percent for alternative E. Treatments under alternatives C and D would not reduce any home range acres to unsuitable.

Table 62. Summary of Existing Conditions and Treatment Effects on CSO Home Ranges in the Wildlife Analysis Area

PAC	Existing suitable Forest System acres	CWHR 4M/4D acres reduced to unsuitable			CWHR density class D reduced to class M				% suitable post project (% acres reduced from existing)	
		Alt A	Alt C	Alt E	Alt A	Alt C	Alt D	Alt E	Alt A	Alt E

PL350	2222 (49%)	29		44					49% (1)	48% (2)

Cumulative Effects Common to Old-forest Species, including the California Spotted Owl

The analysis of cumulative effects of the proposed project evaluates its anticipated impact on Threatened, Endangered, and Sensitive species and Management Indicator Species (MIS) and compares those effects to the existing condition (the existing condition reflected by changes that have occurred in the past) within the 115,185 acre wildlife analysis area. Past actions in the area include timber harvest, wildfires, recreation use, wildlife habitat improvement, grazing, and mining. Past timber harvesting on National Forest and private land, together with wildfires, have created a mix of vegetation types and age classes across the wildlife analysis area that has shaped the distribution of old-forest and early seral wildlife species, as reflected by the existing vegetative condition.

The past management history of the Keddie Ridge Project area has strongly influenced stand structure, species composition, fuels, and potential fire behavior at both stand and landscape levels. Fire exclusion and extensive drought-related mortality has created relatively homogeneous areas typified by small even-aged trees existing at high densities. High-density stands are more susceptible to density-dependent mortality driven by drought and insect and disease infestations. Despite many past salvage treatments to remove drought-related mortality, much of this material has fallen over in the last 17 years and become dead and down fuel with high fuel loadings. The high densities of small trees and high fuel loads contribute to continued accumulation of surface, ladder, and canopy fuels, and this accumulation increases the potential for stand-replacing high-severity fire events.

Timber harvest and related activities on NFS lands from 1980 to 2010 affected approximately 27,120 acres in the 115,185 acre wildlife analysis area (approximately 17 percent). Various silvicultural prescriptions were employed, including regeneration (clearcut), selection cut, overstory removal, sanitation cut, commercial thinning, and sanitation salvage (appendix F, table F-1).The majority of these acres were not subject to any harvesting).Site preparation for planting, pre-commercial thinning, and underburning were also part of the timber harvest activities (appendix F). Many of these harvest activities (clearcut, overstory removal, thinning) have resulted in either loss of suitable habitat (stands taken below 40 percent canopy cover) or reduction in habitat value through reductions in canopy cover and removal of stand decadence. These past actions resulted in reduced canopies and simplified overstory and understory structure within treated stands, which could have increased overall habitat diversity at the landscape level at the time of implementation. In summary, the timber/fuels/vegetation projects in the wildlife analysis area focused on even-aged (clearcut, overstory removal) forestry in the 1970s and 1980s, then switched to sanitation and single tree selection, and then to commercial thinning and fuels reduction in the 1990s. This change in focus, brought on by changes in management guidelines (USDA 1988, 1993a, 2001b, 2004b) has created habitat conditions that support the wildlife populations currently present in the wildlife analysis area.

Private land logging activities in the wildlife analysis area that have occurred since 1997 include 550 acres of shelterwood removal; 1,133 acres of commercial thinning; 15,908 acres of selection cut; 1,655 acres of salvage; and 320 acres of clearcutting (Appendix F, table F-2). Approximately 307 of the 320 acres of clearcut harvest activity occurred in 1997, while the selection harvesting (similar to an overstory removal cut) has been occurring consistently almost every year. Clearcuts created early seral habitat and will remain as early seral (grass/forb/brush/ seedling-sapling) for at least the next 10–20 years. After year 20, conifers may start to dominate the vegetative cover, and by year 50, should be classified as size class 3 trees (6–11 inches DBH). With brush control and release activities, which would be commonplace on private lands, trees could attain this size class earlier than 50 years. Selection harvest usually results in opening up the stand while maintaining forested cover, providing for an uneven-sized stand with scattered brush understory throughout. Thus, past management actions on private lands have provided for an uneven-aged continuous forest cover across the private land landscape.

There have been approximately 11,486 acres of wildfires in the wildlife analysis area since 1979. These fires have ranged in size from 17 acres up to 7,048 acres (which was the Moonlight Fire in 2007). These wildland fires burned at high intensity and created large, monotypic openings of early seral brush habitat within the forest that contribute to large-scale fragmentation of continuous forest cover. Specifically, the Moonlight Fire burned within 4,493 acres of suitable habitat, reducing 3,756 acres to an unsuitable state (CWHR 4P or SMC 1). Much of the areas that experienced wildfires in the analysis area are currently occupied by conifer plantation, montane chaparral, and hardwood forest. Brush fields within and between the plantations support very decadent, impenetrable brush. Large brush fields created by wildfire are used extensively by early seral and midseral wildlife species but not used by species requiring old forest and continuous forest conifer cover. Approximately 2,332 acres of under burning for fuel reduction have been conducted within the wildlife analysis area since 1980, resulting in reduced levels of down slash, increased grass/forb growth and regenerated younger age class of brush species.

Since 2001, it is estimated that approximately 20 percent of the commercial woodcutting permits issued for the Mt. Hough Ranger District occurred in the Keddie Ridge Project area, amounting to approximately 9,278 cords of wood. Commercial woodcutting in the past usually consisted of cutting on and removing existing cull decks, which are manmade habitat features on the landscape used by various mammalian species (including mesocarnivores) for cover and den sites. The removal of these features reduces down woody component availability for owl prey species. It is estimated that, since 2001, approximately 25 percent of the Christmas tree permits issued for the Mt. Hough Ranger District occurred in the Keddie Ridge Project area, amounting to approximately 4,949 permits.

The Personal Use Firewood Program on the Plumas National Forest is an ongoing program that has been in existence for years. This program allows the public to purchase a woodcutting permit and remove fuel and firewood from National Forest System lands. A 9-year average (2001–2009) for the Mt. Hough Ranger District indicates that 2,525 permits were issued annually, resulting in the average annual sale of 5,049 cords of wood on the district. Much of this wood material either consists of down logs found in the forest, along forest roads, and within cull decks created by past logging operations, or as standing snags. The Keddie Ridge Project area is open to woodcutting. Snags and logs would continue to be removed, resulting in the cumulative loss of these habitat components across the landscape, negatively affecting those species dependent on such structures. Snags are recruited annually from live trees through natural processes at a rate that may sustain this loss in the analysis area; snag and log removal is required within a short distance from open roads when these structures pose a safety hazard.

Recreational activities in the wildlife analysis area contribute to cumulative effects on wildlife in terms of increased levels of human disturbance and noise that can result in displacement of wildlife species from selected habitats. The displacement is usually temporary and seasonal, but if disturbance occurs during critical periods (nesting season, winter), effects can be longer term. Most of the recreation use in the wildlife analysis area consists of dispersed activities (by both individuals and small groups) such as hiking, horseback riding, mountain biking, dirt biking, pleasure driving, ATVs, hunting, fishing, camping, rock hounding, mining, and firewood gathering.

Present and ongoing projects occurring in the boundary of the Keddie Ridge wildlife analysis area include the Maidu Stewardship Project, Canyon Dam Fuel Reduction and Forest Health Project, Empire Vegetation Management Project, Moonlight Fire Recovery and Restoration Project, Plumas Fire Safe Council Projects, and Natural Resource Conservation Service (NRCS) Projects.

Maidu Stewardship Project—Project treatments include: approximately 550 acres of commercial and non-commercial thinning to improve Oak habitat; 405 acres of commercial and non-commercial thinning to reduce hazardous fuels, approximately 325 acres of enhancing habitat for culturally important plants. Treatments were initiated in 2006 and are expected to continue through 2016.

Canyon Dam Fuel Reduction and Forest Health Project—Project treatments include: approximately 147 acres of hand thinning, piling, and burning was initiated in fall of 2010 and will be completed over 3 to 5 years. In addition, 488 of mechanical thinning and will be initiated in 2011 and completed over 3 to 5 years. Follow-up prescribed fire treatments will be initiated in 2012 and completed over 3 to 5 years.

Empire Vegetation Management Project—Project treatments include: approximately 121 acres of group selection timber harvest; 430 acres of DFPZ mechanical thinning; 133 acres of Individual Tree Selection (ITS) mechanical thinning; and 144 acres of mastication. These treatments will be initiated in fall 2010 and would be completed over 3-5 years. Follow-up prescribed fire treatments will be initiated in 2012 and completed over 3-5 years.

Moonlight Fire Recovery and Restoration Project—Approximately 7,048 acres of the fire burned within the analysis area. Project treatments include: approximately 330 acres of post-fire roadside hazard tree removal and 70 acres of post-fire salvage harvest. These treatments are ongoing and anticipated to be complete by the end of 2010.

Plumas Fire Safe Council Projects—These projects are located on private lands surrounding homes and are currently being implemented by the Plumas Fire Safe Council. Project treatments include approximately 294 acres of a combination of hand thinning, piling, and burning, mastication, and some removal of commercial and non-commercial forest products.

Natural Resource Conservations Service (NRCS) Projects—These projects are located on private lands and are currently being implemented by Natural Resource Conservation Service (NRCS). Project treatments include approximately, 1,960 acres of a combination of hand thinning, piling, and burning, mastication, and some removal of commercial and non-commercial forest products.

Two of these ongoing projects, Canyon Dam and Empire, would result in some reduction of suitable CWHR 4M, 4D, 5M, and 5D stands. Based on the BA/BE completed for these projects (USDA 2006, 2007a) the net reduction of suitable habitat after treatment within the Keddie Ridge Project analysis area is presented in Table 63.

Table 63. Empire Project and Canyon Dam Project Treatment (Tx) Effects on Old-Forest Suitable CWHR in the Wildlife Analysis Area

Empire Project						Canyon Dam Project	
DFPZ Tx effects		ITS Tx effects		GS Tx effects		Mech. Thin effects	
	acres		acres		acres		acres
4M–4P	155	**4D–4M**	161	**4M–SMC 1**	44	**4D–4M**	90
4D–4P	228	**5D–5M**	3	**4D–SMC 1**	47	**5D–5M**	200
5M–5P	24			**5M–SMC 1**	19	**4M–4P**	75
Total	407		164		110		365

Therefore, the Empire Project would reduce 517 acres of suitable habitat to an unsuitable state (CWHR 4P or MCP) following DFPZ and GS treatments. Canyon Dam would reduce 75 acres to unsuitable state following mechanical thinning treatments. The acres shown in Table 63, when pooled with the acres presented in Table 59 showing CWHR change after implementation of the Keddie Ridge Project alternatives, provides the total expected cumulative CWHR change in size-density class 4M, 4D, 5M, 5D.

The Empire and Canyon Dam projects would affect three spotted owl territories – PL170, PL202, and PL350 but no PAC acres would be treated. Fourteen acres of suitable habitat (4M/4D-10 acres, 5M-4 acres) in the HRCA for PL170 would be reduced to unsuitable following GS treatment under the Empire

Project. The 500-acre core area for PL170 would also see a slight reduction in suitable habitat – 8 acres of 4M reduced to SMC 1. The 1000-acre home range for all three territories would experience a reduction of suitable habitat from these projects. The Empire Project would reduce 254 acres of habitat in the home range of PL170 to unsuitable (227 acres in 4M, 27 acres in 5M) and 24 acres of habitat in the home range of PL202 to unsuitable (21 acres in 4M/4D, 3 acres in 5M). The Canyon Dam Project would reduce 26 acres of 4M habitat in the home range of PL350 to a 4P (unsuitable) state.

The only future foreseeable project that would potentially affect old forest habitat in the wildlife analysis area is the Belden HFQLG Project. Project Treatments include: Approximately 605 acres of Defensible Fuel Profile Zone treatments, 105 acres of Area thinning treatments, and potentially 81 acres of group selection. The exact amount, location, and design criteria for these treatments have yet to be determined but, based on past HFQLG project effects, there is expected to be a cumulative effect to some CWHR 4M, 4D,5M, and 5D stands (i.e. reduction to unsuitable or more open canopy conditions) following implementation of this project.

The documented range expansion of the barred owl has been hypothesized as a contributing factor in the decline in northern spotted owls, through both hybridization as well as replacing the spotted owl in some areas. It is thought that this range expansion and subsequent northern spotted owl displacement can be a result of forest fragmentation and the barred owl's ability to adapt better to a mosaic of habitats. It is suspected that barred owl expansion into the range of the California spotted owl is occurring due to these same reasons.

Barred owls have expanded their range in California as far south as Sequoia National Park, and in recent years the known range of barred owls has expanded 200 miles southward in the Sierras (USDI 2006). The U.S. Fish and Wildlife Service has concluded that barred owls constitute a threat to site occupancy, reproduction, and survival of the California spotted owl, but that there is currently not enough information to conclude that hybridization with barred owls poses a threat (ibid.).

According to the most recent annual report of the Plumas-Lassen Administrative Study (Keane 2010) based on historical and current occurrence records, there have been a minimum total of 53 individual barred owl records across the Sierra Nevada. This includes a minimum total of 19 records in the PLS study area, a portion of which is located in the Keddie Ridge wildlife analysis area. The pattern of records suggest that barred owls have been increasing in the northern Sierra Nevada between 1989-2009 and are now present in low, stable numbers in the PLS study area. No barred owl detections have occurred within the wildlife analysis area.

Determination

The Forest Service has determined that the action alternatives of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the California spotted owl.

Alternative B (No Action)

Direct Effects

There would be no direct effects on the spotted owl or existing spotted owl habitat. No activities would occur that would cause disturbance to nesting or foraging birds.

Indirect Effects

This alternative would have little immediate impact to the species. Stands are currently relatively homogeneous areas typified by small even-aged trees existing at high densities. In the denser stands, habitat values may not reach a point of providing high habitat quality as competition would slow conifer growth and is likely to result in an increase in mortality. Of particular concern is mortality within the larger trees. The development of a multi-storied stand would be slowed and based on the conditions of many stands (single cohorts), that particular habitat feature may not develop without some stand altering activity such as fire or mortality from insects, drought or a combination of factors.

Dense stand conditions may result in an increase in conifer mortality, predominantly among the larger trees that are at a greater risk (due to increased competition for resources). The actual risk is unpredictable as the level of risk is directly tied to stochastic events such a weather and fire. The increase in conifer mortality could indirectly benefit the owls, as the increased decadence would have a positive effect on prey base numbers and overall habitat values.

The indirect effects of no action would include an increased risk for future wildfire and related impacts on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and could create a more intense burn and would result in higher severity effects to vegetation and habitat. Increased rates of spread would result in potential loss of suitable owl nesting habitat and other important habitat attributes such as large trees and snags and down woody material. Thus, under alternative B, suitable habitat for productive owl sites as a result of fire could become patchy or unevenly distributed, and the abundance of owls in the wildlife analysis area could decline.

Cumulative Effects

The no action alternative for the Keddie Ridge Project would not provide for the long-term protection of spotted owl habitat from catastrophic fire. There would be no actions designed to reduce the risk of high-intensity wildfire. Total wildfire acres and high-intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted for the SNFPA Final EIS 2001) which could lead to lower owl abundance in the wildlife analysis area compared to existing conditions. There would be no thinning to enhance the growth of dominant and codominant trees that may provide future habitat availability.

Recreational activities in the wildlife analysis area contribute to cumulative effects on wildlife in terms of increased levels of human disturbance and noise that can result in displacement of wildlife species from selected habitats. The displacement is usually temporary and seasonal, but if disturbance occurs during critical periods (nesting season, winter), effects can be longer term. Most of the recreation use in the wildlife analysis area consists of dispersed activities (by both individuals and small groups) such as hiking, horseback riding, mountain biking, dirt biking, pleasure driving, ATVs, hunting, fishing, camping, rock hounding, mining, and firewood gathering.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the California spotted owl.

Northern Goshawk

All Action Alternatives (A, C, D, and E)

Direct Effects

The analysis of direct effects on northern goshawk is focused on known PACs up to and including the 2005 surveys. The effects on other potentially suitable nesting and foraging habitat outside of PACs are discussed in the "Indirect Effects" section below. No direct effects on northern goshawk are expected because of the following factors:

- Goshawk PACs would not be entered for the Keddie Ridge Project. Currently, there are 8 goshawk PACs (2,149 acres) in the Wildlife analysis area. Five goshawk PACs overlap with spotted owl PAC habitat (goshawk nesting habitat requirements are similar to California spotted owl nesting and foraging requirements [(USDA 1999a), page 3-106]).
- Limited Operating Periods (LOPs) would be implemented which would not allow treatment activities and use of haul roads within 0.25 mile of active nest sites from February 15 to September 15. The LOPs are expected to eliminate effects from increased human activity and vehicle and equipment noise. If new northern goshawk activity centers, such as nests or young, are detected in future surveys or project activities, PACs would be delineated and applicable resource protection measures (such as LOPs) would be applied.
- No new road construction would occur in northern goshawk PACs. For any road reconstruction in PACs, a LOP would be applied to all goshawk activity centers.

The analysis of direct effects is based on data gathered during the 2005 survey. Surveys were repeated in 2006 to complete the two-year survey effort. The proposed treatments could occur in late summer 2011 and continue an additional 5 years. There is the potential that goshawks could establish new territories (activity centers) during project implementation that would not be protected as PACs.

Indirect Effects

Based on the vegetation map and CWHR model, about 40,935 acres of National Forest System lands in the wildlife analysis provide high nesting capability for the northern goshawk (CWHR size/density classes 4M,4D,5M,5D), and an additional 400 National Forest System acres provide moderate nesting capability (Eastside pine 4M,4D,5M,5D, red fir 4M,4D)(Table 59). The total acres of suitable goshawk habitat in the wildlife analysis area that would remain after implementation of each action alternative is basically the same as presented in Table 61above, with the exception that this table includes an additional 34 acres of red fir 5M and 5D, which is not considered suitable goshawk habitat. The post-project CWHR changes summarized in Table 59 are based on the silviculture prescription assigned to each CWHR stand within treatment units (refer to chapter 2 for prescription details for each alternative). Prescriptions are unique and the variables that change are canopy closure and general retention size for trees.

Changes to suitable goshawk nesting habitat in CWHR size/density classes 4M and 4D as a result of implementing project activities would occur under all action alternatives. Approximately 3,065 acres of 4M and 4D habitat is proposed for treatment under each alternative. Prescriptions that would result in 4M and 4D stands reduced to an unsuitable state (4P or SMC 1) fall within some DFPZ units and all group selection units in alternatives A and E. Alternative A would reduce 818 acres of 4M/4D stands to a 4P state (256 acres from 4D, 562 acres from 4M). Group selection treatments under alternative A would reduce an additional 234 acres to a SMC 1 condition (approximately 82 acres from 4D and 152 acres from 4M). Alternative E would reduce 1,082 4M/4D acres to a 4P state (361 acres from 4D, 721 acres from 4M). Group selection treatments under alternative E would reduce an additional 306 acres to an SMC 1 condition (approximately 85 acres from 4D and 158 acres from 4M). Alternative C would reduce approximately 234 acres of 4M to a 4P state thru thinning 12 inches DBH or smaller trees and creating open (below 40 percent) canopy cover conditions. No stands treated under alternative D would be reduced to an unsuitable state.

The amount of 4D stands reduced to a 4M condition (i.e. canopy closure after treatment would be 40-60 percent) under each alternative would be as follows—alternative A-233 acres, alternatives C and D-553 acres, and alternative E-125 acres.

Under all alternatives, the majority of DFPZ and area thinning treatments applied to CWHR 4M and 4D stands would result in no change to CWHR size class or canopy closure (CC). Of the approximate 3,065 acres of 4M and 4D habitat proposed for treatment, 92 percent and 100 percent under alternatives C and D, respectively, would continue to provide suitable foraging conditions for the northern goshawk. No group selection would occur under these two alternatives and treatments such as light thinning, mastication, hand-thinning, underburning would maintain these stands in a suitable CWHR state. Alternative A and alternative E, which would implement group selection and heavier DFPZ treatments, would maintain 66 percent and 57 percent, respectively, of treated 4M and 4D acres in a suitable condition.

Suitable nesting habitat in CWHR size/density classes 5M and 5D proposed for treatment under all alternatives, with the exception of group selection units, is expected to remain suitable for the goshawk (i.e., no change or reduced to 5M). Approximately 1,303 acres of 5M and 5D is proposed for treatment under each action alternative. Mechanical thinning in 140 acres of 5D, under alternatives A, C, and E, would reduce these stands to a 5M condition. Mechanical treatments under alternative D would reduce 130 acres of 5D to 5M. As stated above under spotted owl effects, a small percentage of GS acres would fall within size and density class 5M stands considered highly suitable for nesting goshawks. GS units under alternative A would treat approximately 34 acres of 5M habitat. Alternative E would treat, thru GS, approximately 60 acres of 5M. Unique prescriptions associated with each alternative more fully identifies the effects of treatments to 5M and 5D structural elements. Alternative E would result in the heaviest treatments, with up to 30 inch DBH trees removed while maintaining a 40 percent CC. Prescriptions under alternative A would adhere to an upper diameter limit of either 20 or 24 inch DBH trees and would maintain a 40-50 percent CC. Alternative D prescribes removal of up to 20 inch trees, leaving 50 percent CC. Alternative C, the noncommercial alternative, would have the lightest treatment, thinning to 12 inches DBH and maintaining 40-50 percent CC in 5M and 5D stands.

Improving forest health is one of the objectives of the Keddie Ridge Project and this includes improving vigor of residual trees by reducing stand density and competition. An important design element common to all action alternatives that would help meet such objectives is biomass (less than or equal to 10-inch trees) removal within mechanical thin units. This size class in a stand provides complexity and structure, as well as the diverse microclimates that goshawks seek to control exposure and changes in ambient temperature for roosting. On average, the following percentage of stand biomass would be retained in mechanical thin units: under alternatives A and E 27 to 30 percent in CWHR size class 4 and 17 to 22 percent in CWHR size class 5. Alternatives C and D would retain, on average, more biomass in these same units; 41 to 48 percent in CWHR size class 4 and 34-44 percent in CWHR size class 5.

Group selection treatments, as proposed under alternatives A and E, would create early seral stages and would contribute to heterogeneous stand structures that may be more resilient to disturbance events (such as fire, drought, and insect and disease infestations) on the landscape scale. The treatment would not result in areas that prevent access to adjoining suitable habitat. By design, group selections make up approximately 11.4 percent of any given stand. The small size of the groups (0.5 acre to 2 acres) would not preclude goshawks from flying over or around the treated areas. While the implementation of the group selections may not result in fragmentation in the classic sense, they would reduce the value of the habitat within the stand and would likely cause changes in the behavioral use of the territory, particularly with respect to foraging. Allowance would be made to retain up to two of the largest snags per acre in Group Selection Units, unless removal would be necessary for safety and operability. Based on past projects and discussions with Occupational Safety and Health Administration safety representatives, it is likely that the majority of snags would be felled, and very few snags would be left in the 284 acres of group selection under alternatives A and the 326 acres of group selection under alternative E

The 6.8 miles of new temporary non-system roads proposed to be constructed for the Keddie Ridge Project would be decommissioned upon project completion. Thus, no long-term increases in human activities are expected as a result of the action alternatives. No roads would be constructed in PACs.

It is an unknown as to how some of the important prey species (small mammals, birds) preferred by goshawks would respond to opening up forested stands with fuel treatments and group selection units. Based on CWHR modeling, it is known that several bird species respond favorably to either opening up forested stands and/or openings, while some do not (USDA 1999a, appendix I). The increased diversity and edges created by groups within forested stands may provide foraging habitat that would increase use of the landscape by goshawks. The response of prey species, including small mammals and passerine bird use of group openings, is one of the main objectives of the HFQLG post-implementation monitoring that would be conducted by the Pacific Southwest Research Station through the Plumas-Lassen Administrative Study.

Cumulative Effects

Cumulative effects on the goshawk could occur with the incremental loss of the quantity and/or quality of habitat for this species. Overall, increases in recreational use of National Forest System lands, and the use of natural resources on state, private, and federal lands, may contribute to habitat loss for this species. High-intensity stand-replacing fires, and the means by which land managers control them, have contributed and may continue to contribute to loss of habitat for this species.

Refer to the cumulative effects discussion above for the California spotted owl, as well as cumulative effects discussed in the Keddie Ridge Project BA/BE. Cumulative effects discussion focused on past, present, and future actions as they relate to impacts on suitable owl habitat, more specifically CWHR size/density classes 4M, 4D,5M, and 5D. These same CWHR types are considered to provide suitable goshawk nesting habitat. It is not anticipated that the cumulative habitat reduction would result in loss of occupancy and productivity of known goshawk PACs. This is based on the location of project activities in relation to known PACs, no habitat alteration in PACs, distribution of known PACs, and a minimum of 95 percent retention of available suitable nesting habitat distributed across the wildlife analysis area following project implementation.

Determination

The Forest Service has determined that the action alternatives of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the northern goshawk.

Alternative B (No Action)

Direct Effects

There would be no direct effects on the northern goshawk or existing goshawk habitat. No activities would occur that would cause disturbance to nesting or foraging birds.

Indirect Effects

This alternative would have little immediate impact to the species. Stands are currently relatively homogeneous areas typified by small even-aged trees existing at high densities. In the denser stands, habitat values may not reach a point of providing high habitat quality as competition would slow conifer growth and is likely to result in an increase in mortality. Of particular concern is mortality within the larger trees. The development of a multi-storied stand would be slowed and based on the conditions of many stands (single cohorts), that particular habitat feature may not develop without some stand altering activity such as fire or mortality from insects, drought or a combination of factors.

Dense stand conditions may result in an increase in conifer mortality, predominantly among the larger trees that are at a greater risk (due to increased competition for resources). The actual risk is unpredictable as the level of risk is directly tied to stochastic events such a weather and fire. The increase in conifer mortality could indirectly benefit the goshawks, as the increased decadence would have a positive effect on prey base numbers and overall habitat values.

The indirect effects of no action would include an increased risk for future wildfire and related impacts on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and could create a more intense burn which may result in higher severity effects to forested habitats. Increased rates of spread would result in potential loss of suitable goshawk nesting habitat and other important habitat attributes such as large trees and snags and down woody material. Thus, under alternative B, suitable habitat for productive goshawk sites as a result of fire could become patchy or unevenly distributed, and the abundance of goshawks in the wildlife analysis area could decline.

Cumulative Effects

The no action alternative for the Keddie Ridge Project would not provide for the long-term protection of northern goshawk habitat from catastrophic fire. There would be no actions designed to reduce the risk of high-severity wildfire. Total wildfire acres and high-intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted for the SNFPA final EIS (USDA 2001a), which could lead to lower goshawk abundance in the wildlife analysis area compared to existing conditions. There would be no thinning to enhance the growth of dominant and codominant trees that may provide future habitat availability.

Recreational activities in the wildlife analysis area contribute to cumulative effects on wildlife in terms of increased levels of human disturbance and noise that can result in displacement of wildlife species from selected habitats. The displacement is usually temporary and seasonal, but if disturbance occurs during critical periods (nesting season, winter), effects can be longer term. Most of the recreation use in the wildlife analysis area consists of dispersed activities (by both individuals and small groups) such as hiking, horseback riding, mountain biking, dirt biking, pleasure driving, ATVs, hunting, fishing, camping, rock hounding, mining, and firewood gathering.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the northern goshawk.

Mesocarnivores

All Action Alternatives (A, C, D, and E)

Direct Effects

No direct effects to mesocarnivores are expected due to the likelihood of no individuals inhabiting the wildlife analysis area. The indirect effects section below discusses potential effects to existing suitable mesocarnivore habitat as a result of implementing Keddie Ridge Project activities.

Indirect Effects

Refer to the indirect effects discussion for the spotted owl for changes to suitable mesocarnivore habitat (CWHR size-density classes 4M, 4D, 5M, and 5D) as a result of implementing fuel treatments, group selection harvests, and area thinning under each action alternative. The number of denning and foraging habitat acres that could be reduced by each alternative is discussed below.

Table 64 summarizes the project effects to denning and foraging habitat for the fisher. As Table 64 shows, alternatives A and E, due to the heavier DFPZ treatments and group selections proposed, would reduce some acres to an unsuitable state (CWHR 4P or SMC 1). Alternative C, as a result of thinning some stands to below 40 percent canopy cover to meet fuel objectives, would reduce approximately 234 acres to an unsuitable (4P) condition. Alternatives C and D would reduce 684 acres and 693 acres, respectively, of denning habitat to a 5M or 4M state. Acres of 4D/5D reduced to 4M/5M under all action alternatives would be considered suitable foraging habitat for the fisher.

Table 64. Keddie Ridge Project Effects to Fisher Denning and Foraging Habitat

	Denning Habitat acres (CWHR 4D/5D)					Foraging Habitat acres (CWHR 4M/5M)		
	5D→5M	4D→4M	4D→4P	GS*→MCP	Total	4M→4P	GS*→MCP	Total
Alt A	140	65	345	82 (4D only)	**615**	562	186 (4M-152, 5M-34)	**808**
Alt C	131	553	0	no GS	**684**	0	no GS	**0**
Alt D	140	553	0	no GS	**693**	0	no GS	**0**
Alt E	140	129	373	85 (4D only)	**717**	721	218 (4M-158, 5M-60)	**954**

*approximation of GS acres only - exact location and acreage yet to be determined. Group selections would primarily be located in size class 4 stands.

In summary, existing fisher denning habitat treated under alternatives A and E would be reduced by 4.6 percent and 5.3 percent respectively. Alternatives C and D would reduce denning habitat by 5 percent. After factoring in the CWHR density class D stands converted to density class M as a result of treatments (Table 64) alternatives A and E would result in a reduction of suitable foraging habitat by 1.3 percent and 2.4 percent respectively. Alternatives C and D would see an increase of approximately 693 foraging acres from existing conditions as a result of thinning treatments within 5D and 4D stands.

Of the CWHR types considered suitable for the American marten in the wildlife analysis area, only Sierra mixed conifer (SMC) habitat is proposed for treatment. Foraging habitat (SMC4M, SMC5M) proposed for treatment is 3,254 acres. Denning habitat (SMC4D, SMC5D) proposed for treatment is 799 acres. Table 65 summarized the project effects to suitable marten habitat. It is estimated that, under alternatives A and E, no group selection would occur within suitable marten denning habitat.

Table 65. Keddie Ridge Project Effects to Marten Denning and Foraging Habitat

	Denning Habitat acres (SMC 4D/5D)				Foraging Habitat acres (SMC 4M/5M)		
	5D→5M	4D→4M	4D→4P	Total	4M→4P	GS*→SMC 1	Total
Alt A	121	241	240	**602**	556	45 (4M-15, 5M-30)	**601**
Alt C	121	481	0	**602**	234	no GS	**234**
Alt D	111	481	0	**592**	0	no GS	**0**
Alt E	121	126	355	**602**	721	66 (4M-12, 5M-54)	**786**

*approximation of GS acres only - exact location and acreage yet to be determined.

In summary, existing marten denning habitat treated under all action alternatives would be reduced by 5 percent (592-602 acres). Existing marten foraging habitat treated under alternatives A, C, and E would see a reduction of 2 percent, 1 percent, and 3 percent respectively. Alternatives C and D would see an increase of approximately 368 and 592 foraging acres, respectively, from existing conditions as a result of thinning treatments within 5D and 4D stands.

Approximately 13,153 acres (3 percent) of the forest carnivore network are within the wildlife analysis area. The Keddie Ridge Project proposes to treat 134 acres of this network. Hand thin/pile/and burn, mastication, or prescribed fire treatments would fall within 115 network acres (85 percent), resulting in little to no change to existing suitable carnivore habitat. Approximately 19 acres of the carnivore network would be mechanically thinned under all alternatives. Alternatives A and E would reduce 3 acres of SMC4M habitat to a 4P state. All action alternatives would treat less than 1 acre of SMC5D that would result in a 5M condition. No group selection acres are proposed in the carnivore network. In summary, the Keddie Ridge Project's effects on the forest carnivore network would be negligible, due to the small amount of acreage proposed for treatment and little to no change to existing suitable habitat post project.

All new roads that would be constructed in support of the Keddie Ridge Project would be closed upon project completion, thus no long-term increases in human activities are expected. The open road density in the Keddie Ridge Project area would remain the same under all action alternatives (approximately 2.4 miles per square mile), which would still provide low habitat capability for forest mesocarnivores. With implementation of the proposed strategic system of DFPZs, the Keddie Ridge Project would help reduce understory fuel buildup and may reduce the potential for high-severity wildfires, which have a great potential to degrade vast tracts of habitat for the marten and fisher.

Cumulative Effects

Refer to the cumulative effects discussion above for the California spotted owl, as well as the cumulative effects discussed in the Keddie Ridge Project BA/BE. The cumulative effects on forest mesocarnivores could occur with the incremental reduction of the quantity and/or quality of habitat for this species. Overall, increases in recreational use of National Forest System lands, and the use of natural resources on state, private, and federal lands, may contribute to habitat loss for this species. High-severity stand-replacing fires, and the means by which land managers control them, have contributed, and may continue to contribute to loss of habitat for these species.

The action alternatives would not increase any large-scale, high-contrast fragmentation above existing levels. The cumulative effect of private land clearcuts and selective thinnings, older National Forest System land plantations, the large brush fields created by past wildfires, together with implementation of DFPZs and group selection (alternatives A and E only) under the Keddie Ridge Project would result in increased "patchwork" of open habitat and young age class vegetation between mature forested stands within the analysis area. This would increase edge effects and possibly increase potential risks to forest interior species movement and use in the wildlife analysis area. Thus the Keddie Ridge Project would act cumulatively with past actions to slightly reduce the connectivity of habitat within the wildlife analysis area, although connectivity would remain and improve over time as conifer cover is restored through natural processes and increased protection from high-severity fire. Connectivity of dense forest habitat (moderate and dense stands in size classes 4 and 5) is shown in Figure 12.

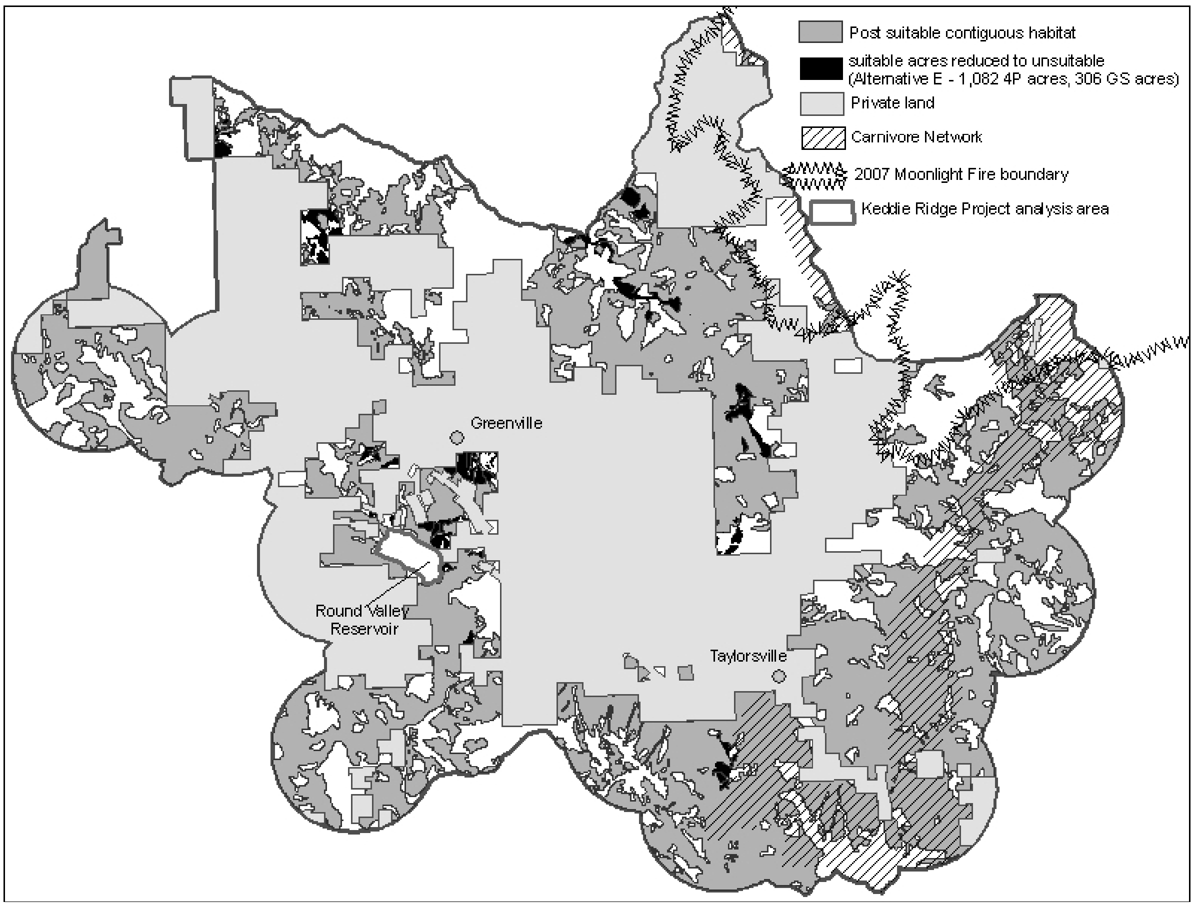

Figure 12. Mesocarnivore Contiguous Suitable Habitat Available (CWHR Size-Density Classes 4M, 4D, 5M, 5D) Following Implementation of the Keddie Ridge Project (Alternative E Effects Shown, Which is Maximum Area Reduced to Unsuitable Compared to All Alternatives)

Figure 12 shows 39 blocks of contiguous habitat ranging in size from 25 acres to 12,470 acres, with the average block size over 1,000 acres. Of all action alternatives, alternative E would have the largest effect on suitable carnivore habitat. Implementation of any of the action alternatives would result in little change to available contiguous suitable habitat.

Based on the direct and indirect effects, implementation of all action alternatives would contribute to cumulative effects on mesocarnivores and mesocarnivore habitat. Post-treatment amounts of suitable mesocarnivore habitat would provide similar numbers and size blocks of contiguous habitat as the existing condition. The reduction of 4.6-5.3 percent of suitable denning habitat and the reduction of 1.3-2.4 percent (alternatives A and E) of suitable foraging habitat for the fisher (table 59) would not cause any large-scale fragmentation of suitable habitat. There would be a cumulative reduction in habitat for the next 50 years in fuel treatments to 50+ years in group selection areas. Implementation of alternatives A and E would result in the highest risk of all alternatives to mesocarnivore habitat in the short-term and greatest uncertainty about future mesocarnivore activity.

Alternative C would reduce suitable foraging habitat by approximately 1 percent. Implementation of alternative D would not result in additional unsuitable habitat. Alternatives C and D would reduce a small percentage of denning habitat to a foraging condition as a result of treatments. Therefore, these alternatives would also present a level of risk to mesocarnivore habitat in the short-term and uncertainty about future mesocarnivore activity but this level of risk would be less than the alternatives A and E. Based on known detections of marten on the Plumas National Forest, no changes in marten occupancy or populations on the Forest would occur.

Determination

The Forest Service has determined that, for all action alternatives, the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the American marten or Pacific fisher.

Alternative B (No Action)

Direct Effects

There would be no direct effects on mesocarnivores or existing mesocarnivore habitat. No activities would occur that would cause disturbance to denning or foraging carnivores.

Indirect Effects

This alternative would have little immediate impact to the species. Stands are currently relatively homogeneous areas typified by small even-aged trees existing at high densities. In the denser stands, habitat values may not reach a point of providing high habitat quality as competition would slow conifer growth and is likely to result in an increase in mortality. Of particular concern is mortality within the larger trees. The development of a multi-storied stand would be slowed and based on the conditions of many stands (single cohorts), that particular habitat feature may not develop without some stand altering activity such as fire or mortality from insects, drought or a combination of factors.

Dense stand conditions may result in an increase in conifer mortality, predominantly among the larger trees that are at a greater risk (due to increased competition for resources). The actual risk is unpredictable as the level of risk is directly tied to stochastic events such a weather and fire. The increase in conifer mortality could indirectly benefit mesocarnivores, as the increased decadence could provide higher quality denning areas, support larger carnivore prey populations, and provide safer movement corridors.

The indirect effects of no action would include an increased risk for future wildfire and related impacts on habitat development and recovery. The fuel loads that would be left by this alternative would make potential wildfires in the area difficult to suppress and could create a more intense burn. Increased rates of spread would result in potential loss of carnivore denning and foraging habitat and other important habitat attributes such as large trees and snags and down woody material. Thus, under alternative B, suitable carnivore habitat as a result of fire could become patchy or unevenly distributed, resulting in less desirable conditions for martens and fishers to become re-established in the wildlife analysis area.

Cumulative Effects

The no action alternative for the Keddie Ridge Project would not provide for the long-term protection of carnivore habitat from catastrophic fire. There would be no actions designed to reduce the risk of high-intensity wildfire. Total wildfire acres and high-intensity wildfire acres are anticipated to increase from current levels under this alternative (based on analysis conducted for the SNFPA final EIS (USDA 2001a), which could lead to lower owl abundance in the wildlife analysis area compared to existing conditions. There would be no thinning to enhance the growth of dominant and codominant trees that may provide future habitat availability.

Recreational activities in the wildlife analysis area contribute to cumulative effects on wildlife in terms of increased levels of human disturbance and noise that can result in displacement of wildlife species from selected habitats. Such displacement is usually temporary and seasonal. Most of the recreation use in the wildlife analysis area consists of dispersed activities (by both individuals and small groups) such as hiking, horseback riding, mountain biking, dirt biking, pleasure driving, ATVs, hunting, fishing, camping, rock hounding, mining, and firewood gathering.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the American marten or Pacific fisher.

Mountain Yellow-legged Frog

All Action Alternatives (A, C, D, and E)

Direct Effects

Potential direct effects from the Keddie Ridge Project include impacts to individual mountain yellow-legged frogs (MYLFs) during activities. Possible direct effects from the proposed actions on Forest Service R5 aquatic sensitive species include crushing of individuals if they are present during project activities. The use of a feller buncher within RHCAs has the potential of directly injuring or killing frogs. Although skyline logging is considered to have minimal ground disturbing effects, falling of trees can result in crushing, injuring, or killing of animals that occur where trees fall. The potential for direct impacts to individuals is greatest during wet periods and in early fall, when frogs are most likely to disperse from aquatic habitats.

A 3-year telemetry study conducted on the PNF found that MYLF have very limited movements into upland habitats or adjacent riparian areas (Wengert et al. 2006). The study concluded that off-stream channel movements were very rare and that in-stream movements within and up and down the wetted stream channel were common and frequent traits of MYLF behavior. Therefore, the Keddie Ridge Project design features and standard management requirements, which include RHCA equipment restriction zones, best management practices (BMPs) to prevent water quality degradation (appendix H) and riparian management objectives standards (appendix E) should provide adequate protection to minimize impacts to MYLFs (if present) within riparian or upland habitats. Potential direct effects are expected to be negligible to MYLFs due to the likelihood, based on survey results, that populations are not present in treatment areas.

Indirect Effects

Riparian habitats would be entered during DFPZ and area thinning treatments for the purpose of restoring, maintaining, or improving riparian habitat conditions. Treatments would include the removal of encroaching conifer vegetation (up to 20 inches in diameter) through mechanical means, hand thinning, mastication, and underburning. Group selection would avoid RHCAs. Approximately 1,279 acres of RHCAs would be entered for treatment under the action alternatives.

Table 66. Approximate RHCA Acres Proposed for Treatment

RHCA Prescription	RHCA acres treated by alternative			
	Alt A	Alt C	Alt D	Alt E
20" UDL*/50% CC	504		281	549
12" UDL/50% CC	45	550	155	
masticate <10" trees	155	133	133	133
underburn	308	308	308	308
HPB* <8" trees	267	288	363	288
Total RHCA acres	1279			

*UDL=upper diameter limit. *HPB=handthin, pile, and burn

"Equivalent Roaded Acres" (ERA) is a conceptual unit of measure used to assess ground-disturbing activities. One acre of road surface equals one Equivalent Roaded Acre or ERA. The proposed fuel treatment and area thinning activities would increase ERA values in the subwatersheds where treatments would occur. Increases in ERA may lead to detrimental effects to MYLF stream habitat, including erosion from treated hillsides and increased delivery of sedimentation into streams. Primary factors leading to this would include a reduction of canopy cover, ground disturbance (particularly due to road effects), and loss of ground cover. Disturbances are often added together to determine a cumulative ERA for individual watersheds. This is discussed in the following cumulative effects section.

Equipment exclusion zones in RHCAs, based on existing RHCA buffer widths and slope class (Table 9), would lessen the extent of skid trail creation within RHCAs. Areas in which mechanical harvest activities would be allowed within RHCAs have the potential to increase the extent of disturbed, displaced, or compacted soils. Such soil conditions would have a potential adverse effect on watershed conditions by increasing sedimentation delivery into streams. Indirect effects due to skidding would likely not occur or would be minimal. Implementation of design criteria specific to skid trails in RHCAs (Table 9), Standard management requirements, and BMPs would help mitigate and prevent increased compaction, erosion, and sedimentation.

Prescribed fires would not affect canopy cover in RHCAs, but they could remove some ground cover. The implementation of standard protection measures (design criteria, SMRs, BMPs) would help minimize indirect effects on amphibians and reptile species. Burns occurring before the first soaking rains of the fall are least likely to directly affect amphibians because the frogs would be in the RHCAs at that time. Burns occurring during the spring would be more likely to cause direct effects on amphibians and reptiles, as individuals would be more likely to be moving outside the RHCAs at that time.

Treatments in RHCAs may increase the vigor of riparian vegetation due to increased water yield and reduced competition by conifers. By removing conifers from RHCAs, short-term decreases in channel shading may occur that could affect stream temperatures until riparian vegetation fills these voids. In-channel large woody debris (LWD)(trees greater than 12 inches diameter) would be sustained because no natural in-channel debris would be removed. Future recruitment of LWD would be encouraged through release of the existing conifers and snag retention standards.

Table 7 states the design criteria for RHCA treatments under all action alternatives. The retention of 20-inch or larger trees (greater than or equal to 12 inches under alternative C), 50 percent or greater canopy cover, all hardwood and riparian species, and sufficient amounts of residual surface fuels (including large woody debris) within RHCAs would indirectly benefit MYLFs by maintaining suitable habitat values while creating riparian conditions that would be less susceptible to high-severity, stand-replacing fire. Large fires have the potential to create large-scale, high-contrast fragmentation across the landscape, which could remove suitable MYLF habitat, isolates habitat patches, and creates large openings that may prevent species occupancy, emigration, and immigration. The action alternatives would reduce the long-term threat of stand-replacing fires, which would offset their short-term minor effects (USDA 2003).

Herbicide Hazard Analysis

An herbicide is a pesticide that kills plants or inhibits their growth. To evaluate the effects of herbicides on wildlife, it is critical to consider several factors such as toxicity, exposure, dose, and the biology and behavior of species that could potentially be exposed to the herbicide. Toxicity is the potential a pesticide has for causing harm to a specific species or group of species.

Alternatives A and D propose to treat three noxious weed species (starthistle, Canada thistle, hoary cress) with herbicides. Two herbicides would be used: aminopyralid (i.e. Milestone® or an equivalent formulation) to treat dry and upland sites greater than 15 feet from the water's edge and the aquatic formulation of glyphosate (i.e. Accord™ or an equivalent formulation) for lowland treatments (between 0-15 feet from the water's edge). Aminopyralid would be applied to approximately 61.5 acres infested with Canada thistle and starthistle. A backpack sprayer would be used to spray upland infestations along roads, skid trails, and landings. Glyphosate would be applied to approximately 1 acre to control Canada thistle and hoary cress. A wick applicator (in riparian areas) or backpack sprayer (on roads and landings) would be used to selectively apply this herbicide. The following additives would likely be added to herbicide formulations to increase efficacy of treatments: non-ionic modified vegetable oil surfactant (i.e. Competitor® or an equivalent) and water soluble colorant [c] (i.e. Hi-Light™ Blue or an equivalent). The Keddie Ridge Project also proposes to apply a registered borax fungicide (i.e. Sporax or Cellu-treat) to pine stumps greater than 14 inches in diameter in units 45, 46, 49, and 50.

Wildlife may be exposed to herbicides if they are in the vicinity of contaminated surface waters or treated vegetation. The routes of exposure include oral, dermal, and inhalation. Oral exposures might occur through ingestion of contaminated food (such as insects) or water (small puddles during application) or incidental ingestion of contaminated plants during foraging or other activities. Dermal exposures are likely to be most important for burrowing mammals (through contact with contaminated soils) and animals that spend considerable amounts of time within ground vegetation.

Fish and invertebrate exposure rates are based on water contamination rates. Syracuse Environmental Research Associates, Inc. (SERA), under contract to the Forest Service, provides very few studies related to the effects of herbicides on amphibian species. There is extremely limited published data on the relationship of herbicides on mountain yellow-legged frogs. The risk to a variety of aquatic, amphibian, and reptilian species varies with the chemical(s), rate(s), timing, and other factors, which can vary by site condition (Syracuse Environmental Research Associates (SERA) 2003, 2007).

The Syracuse Environmental Research Associates, Inc. risk assessment worksheets for aminopyralid and glyphosate (ibid) evaluated toxicity, dose, and biology of a species and developed a “Hazard Quotient” for a number of scenarios. A hazard quotient is basically a mathematical calculation that is expressed numerically in terms of risk, where neutral risk is equal to 1, and the risk of toxicity increases as the value rises above 1 and decreases as the value drops below 1. For the application rates and application methods (backpack) proposed for noxious weeds under the Keddie Ridge Project, all hazard quotients for the two herbicides are below 1 for all terrestrial and aquatic vertebrate species and aquatic invertebrate species evaluated in the SERA worksheets. There is the potential for an herbicide spill into streams or other bodies of water directly affecting fish and aquatic invertebrates with the potential of a chronic exposure. A spill plan would be followed for herbicide application within the project area. The hazard quotient for wicking application is assumed to be even lower than the backpack sprayer application due to the more direct application and control.

Surfactants are used to facilitate or enhance the absorbing, emulsifying, dispersing, spreading, sticking, wetting, or penetrating properties of herbicides. Competitor® is a non-ionic modified vegetable oil. The assessments of hazards related to surfactants is limited by the proprietary nature of the formulations. Surfactants, by their very nature, are intended to increase the effect of a pesticide by increasing the amount of pesticide that is in contact with the target. This is not synergistic, but more accurately a reflection of increased dose of the herbicide active ingredient into the plant. The “Analysis of Issues Surrounding the Use of Spray Adjuvants with Herbicides” (Bakke 2003) sites technical references which indicate a lack of synergistic effects between surfactants and pesticides which suggest that surfactants don’t increase the toxic effects of herbicides. This paper also listed the results of standard acute aquatic species toxicity testing which indicated that any potential effects to aquatic species would be unlikely under normal application rates.

The colorant Hi-Light™ Blue will be added to the herbicide mixtures prior to the application so that the actual treated area can be readily determined. This helps to prevent skips and overlaps. Hi-Light™ Blue is a water-soluble dye that contains no listed hazardous substances. It is considered to be virtually non-toxic to humans. Its effect on non-target terrestrial and aquatic species is unknown, however its use has not resulted in any known problems. The dye used in Hi-Light™ Blue is commonly used in toilet bowl cleaners and as a colorant for lakes and ponds (Syracuse Environmental Research Associates (SERA) 1997).

Under alternatives A and D, in units 45,46,49, and 50, Borax (Sporax) would be applied to all cut stumps greater than 14 inches DBH. to minimize the susceptibility to *Heterobasidion* root disease. In the most recent risk assessment for Borax (SERA 2006), Boron, the agent of toxicological concern in Borax, was further evaluated. The focus of the evaluation was wildlife's direct consumption from the stump and ingestion of contaminated water. The assessment concluded that the use of Borax on stumps does not present a significant risk to wildlife species under most conditions of normal use, even under the highest application rates.

There is little chance that either glyphosate or aminopyralid is expected to reach streams because of their limited transport mobility, relatively short half-lives, and application criteria, which takes into account the time of year, wind velocity, and period to the next rainfall). Application methods would be aimed specifically to individual noxious weed plants and not applied at a broadcast scale. No change in nontargeted plants and vegetative succession would occur as a result of herbicide application on noxious weeds. The noxious weeds proposed for treatment are highly unpalatable and are not consumed by herbivores, but seed-eating birds, such as goldfinches and pine siskins, could possibly feed on the seeds. In conclusion, no significant adverse wildlife effects associated with the herbicide application alternatives are expected.

Cumulative Effects

The following discussion on watershed conditions within the analysis area is drawn from the cumulative watershed assessment under the Hydrology and Soils section found in this DEIS chapter.

The area defined for the cumulative watershed assessment encompasses 12 sub-watersheds, which are contained in 10 HUC 6 watersheds, all of which contain varying degrees of suitable habitat for MYLFs. The Wolf Creek, Lights Creek, and Indian Creek systems converge in the Indian Valley basin and flow south west draining the assessment area. Indian Creek joins Spanish Creek at the boundary of the assessment area to form the East Branch North Fork Feather River.

The threshold of concern (TOC) is an indicator used to assess the risk of cumulative watershed effects. The TOC is generally expressed as a percentage of watershed area. When the total ERA in a watershed exceeds the TOC, susceptibility for significant adverse cumulative effects is high. The cumulative ERA in a watershed is often expressed as a percent of the TOC. For example, in a 1,000-acre watershed where the

TOC is 12 percent of the watershed area, 100 percent of the TOC represents a condition where the amount of disturbance is similar to 120 acres of road surface.

Following implementation of any of the action alternatives, no subwatersheds would be at or exceed the TOC and only one subwatershed (Upper Cooks) would approach the TOC. The Moonlight Fire and subsequent private salvage harvest activities raised the ERA value in the Upper Cooks Creek subwatershed to 90.2 percent of TOC, and the Keddie Ridge project would raise it another 8 percent. The Round Valley Reservoir subwatershed, the municipal water supply for Greeenville, is projected to experience the greatest increase in ERA—16.3 percent, bringing the ERA value up to 6.83 which equates to 57 percent of the TOC. The increase in ERA values under all alternatives is predicted to range from .01 to 16.3 percent of the TOC, depending on the subwatershed. This would result in cumulative ERA values ranging from 12.8 to 97.6 percent of the TOC. ERA values under alternatives C and D would be slightly less than alternatives A and E due primarily to the no group selection proposed.

The HFQLG Act Record of Decision, and its associated Scientific Analysis Team guidelines for DFPZ construction, and the SNFPA Record of Decision's aquatic strategy for DFPZ maintenance, would not only prevent or strictly control any additional impacts on frog habitat, but would result in actual habitat restoration and enhancement for some streams (USDA 1999b). It is unlikely that the proposed activities would be a significant addition to cumulative effects on the frog species, and habitat characteristics would not change to a degree that these effects would limit populations; therefore, there would be very few cumulative effects.

Determination

The Forest Service has determined that the action alternatives of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the mountain yellow-legged frog. This determination is based on project design features that would lessen and minimize impacts to the MYLF and suitable habitat which include: 1) incorporation of RHCA equipment restriction zones, 2) implementation of best management practices, and 3) implementation of soil and water standards (riparian management objectives).

Alternative B (No Action)

Direct Effects

There would be no direct effects on MYLF habitat because no activities would occur to cause disturbance to individual frogs or to impact existing habitat conditions.

Indirect Effects

The DFPZ, group selection, and area thinning treatments would not occur under the no action alternative, so there would be no exacted effects on the channel network. The fuel loads left by alternative B could make potential wildfires in the area difficult to suppress and create a more intense burn, which could lead in a potential loss of RHCAs. There would be the potential for RHCAs with high fuel loads to act like chimneys and carry fire up and down the watershed. Typically, burn severity and the effects of wildfire disturbance are often limited in near-stream areas compared to upland areas. The effects of fire adjacent to channels can be devastating to the integrity of stream proper function and condition. Channel degradation, erosion, and sedimentation and the resulting effects on stream and riparian habitats and water quality would likely increase following a stand-replacing fire. Roads in the Keddie Ridge Project area would not be improved for drainage and aquatic species habitat connectivity. Sedimentation from road runoff into the drainages and fragmentation of aquatic habitats would continue.

Cumulative Effects

Cumulative effects from private land use (timber and gravel extraction, livestock grazing, and urbanization) would continue to create water quality problems, including sedimentation and bank cutting.

Determination

The Forest Service has determined that the no action alternative of the Keddie Ridge Project may affect individuals but is not likely to result in a trend toward federal listing or loss of viability for the mountain yellow-legged frog.

USDA Forest Service R5 Management Indicator Species

Hairy Woodpecker

The direct, indirect, and cumulative effect of the Keddie Ridge Project in terms of changes in medium-sized and large-sized snags per acre within green forest habitat would not change from the existing condition, as snags in green forested habitat would only be minimally impacted by DFPZ and Area Thinning Treatments. The primary proposed action that would likely remove snags would be group selection. Alternative A proposes 284 acres of groups selection. Alternative E proposes 326 acres of group selection. Medium (15-30 inches DBH) to large (greater than 30 inches) snags within these group selection acres may or may not remain due to required removal to allow for operability. Additional snag removal that may be required for operability reasons along haul routes and on landings is expected to be minimal. On average, the amount of snags greater than 15 inches DBH existing and that would remain post-treatment within units is 3 per acre. Snag amounts (existing and post-treatment) range from 0 in some units to 12 per acre in others. The design criteria for all action alternatives (chapter 2, tables 5, 6, 7) states that, where available, four of the largest snags (15 inches DBH and 20 feet in height) per acre will be retained. It is determined that the Keddie Ridge Project actions will not alter the existing trend in the ecosystem component for this species, nor will it lead to a change in the distribution of hairy woodpeckers across the Sierra Nevada Bioregion.

Aquatic Macroinvertebrates

Treatments under all action alternatives within RHCAs have the potential to increase the extent of disturbed, displaced, or compacted soils. Such soil conditions would have a potential adverse effect on watershed conditions by increasing sedimentation delivery into streams. Short-term decreases in channel shading and ground cover could occur as well. The implementation of standard protection measures (design criteria, SMRs, BMPs) would help minimize these indirect effects.

Despite the risk of potential adverse effects, the greater long-term benefit of treating RHCAs under the Keddie Ridge Project would be the potential increased protection from catastrophic wildfire. Other effects would include increasing the size of residual trees within RHCAs, preventing potential catastrophic wildfire, reducing future losses of large diameter trees and large woody debris (LWD) to fire, and increasing future LWD recruitment of intermediate to large logs. In riverine systems, debris would help maintain channel stability, decrease flow velocity, trap sediment, and protect banks from erosion (Berg 1998). Within the immediate riparian areas, the physical effects derived from in-channel LWD would be retained because no natural debris would be removed. Future recruitment of LWD, which is structurally important for channel morphology, channel function, and bank stability, would be encouraged through snag retention requirements and release of existing live conifers. The increase in subwatershed ERA values as a result of project activities proposed under all alternatives (refer to the Hydrologyand Soils section of this DEIS for further discussion of ERA) is not likely to result in noticeably changes to stream flow or sedimentation delivery. As well, based on incorporation of RHCA equipment restriction zones and implementation of best management practices existing water surface shade conditions and riparian LWD is expected to be maintained following treatments.

The Keddie Ridge Project cumulative watershed effects analysis concluded that, following implementation of any of the action alternatives, no subwatersheds would be at or exceed the threshold of concern (TOC). Thus, suitable riparian conditions for aquatic species would not be susceptible to significant adverse cumulative effects as a result of fuel reduction activities implemented under the Keddie Ridge Project. It is determined that the Keddie Ridge Project’s cumulative impacts are too small to have any affect at the larger scale and thus will not alter the existing trend in the habitat or aquatic macroinvertebrates across the Sierra Nevada bioregion.

Hydrology and Soils

Introduction

A cumulative impact, as defined in 40 CFR 1508.7 is

> *the impact on the environment which results from the incremental impact of the action when added to other past, present, and foreseeable future actions regardless of what agency (Federal or non-federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time (CEQ 1971).*

Cumulative impacts may occur off-site and, in the case of the water resource, may affect downstream beneficial uses of water. Effects can be either beneficial or adverse and result from the synergistic or additive effects of multiple management activities within a watershed (USDA 1988).

Cumulative watershed effects (CWE) analyses have traditionally focused on impacts to downstream beneficial uses. These include aquatic habitat, hydroelectric power generation, and domestic water supplies. New information has come to light that places considerable emphasis on near-stream disturbances and their site-specific biological effects (Menning 1996, McGurk and Fong 1995), as well as the downstream physical effects.

Soil quality analysis standards presented in the Region 5 Forest Service Soil Management Handbook provide threshold values that indicate when changes in soil properties and soil conditions would potentially result in long-term losses to inherent productivity or hydrologic function of the soil (USDA 1995). When threshold values are exceeded for certain soil properties, the resulting condition is termed "detrimental soil disturbance." This analysis addresses downstream cumulative watershed effects as well as site-specific impacts that relate to changes in long-term soil productivity.

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

Direction Relevant to the Project as it Affects Soil Resources

National Forest Management Act (NFMA) of 1976 (which amended The Forest and Rangeland Renewable Resources Planning Act of 1974)

As described in Forest Service Manual Chapter 2550 (USDA 2009b), this authority requires the maintenance of productivity and protection of the land and, where appropriate, the improvement of the quality of soil and water resources. NFMA specifies that substantial and permanent impairment of productivity must be avoided.

National Soil Management Handbook

Forest Service Handbook 2509.18 (USDA 1991) defines soil productivity and components of soil productivity, establishes guidance for measuring soil productivity, and establishes thresholds to assist in forest planning.

Region 5 Soil Management Handbook Supplement

This supplement (R5 FSH Supplement 2509.18-95-1) establishes regional soil quality analysis standards which provide threshold values to indicate when changes in soil properties and soil conditions would potentially result in a significant change in soil productivity, soil hydrologic function, or soil buffering capacity (USDA 1995). The analysis standards are to be used for areas dedicated to growing vegetation. They are not applied to lands with other dedicated uses, such as system roads and trails or developed campgrounds.

The soil quality analysis standards provide for consistent project analyses across the region. These thresholds are used for project analysis but are not a set of mandatory project standards or requirements. When a soil quality indicator exceeds the stated threshold, the result is termed detrimental soil disturbance. The handbook advises that detrimental soil disturbance that affects soil productivity shall not be of a size or pattern that would result in significant change in production potential for the activity area. Analysis threshold indicators for soil productivity include:

- A 10 percent or more reduction in total soil porosity, from that found under natural conditions, corresponds to a threshold soil bulk density that indicates detrimental soil compaction.
- Surface organic matter is to be maintained in amounts sufficient to prevent nutrient cycle deficits and to avoid detrimental physical and biological soil conditions. Fine organic matter (material up to 3 inches in diameter) is to occur over at least 50 percent of the area.

- The threshold for large woody material (logs at least 10 feet long and 12 inches in diameter) is at least 5 well distributed logs per acre.
- Project levels of surface organic matter, including fine organic and large woody material, should not elevate wildfire risk or severity and may be reduced to meet management objectives in fuel breaks.

The R5 Handbook advises that soil hydrologic function is to be analyzed using the R5 Cumulative Watershed Effects Analysis and/or the R5 Soil Hazard Erosion Rating system (USDA 1995). Soil buffering capacity analysis should determine whether materials added to the soil significantly alter soil reaction class, buffering or exchange capacities, or microorganism populations.

Plumas National Forest Land and Resource Management Plan (LRMP)

Forest Plan standards and guidelines provide the relevant substantive standards to comply with NFMA. The 1988 LRMP (USDA 1988) establishes standards and guidelines to prevent significant or permanent impairment of soil productivity, including:

- During project activities, minimize excessive loss of organic matter and limit soil disturbance according to Erosion Hazard Rating (EHR): for EHR of 4-8, conduct normal activities; for EHR of 9-10, minimize or modify use of soil disturbing activities; for EHR of 11-13, severely limit soil-disturbing activities.
- Determine adequate ground cover for disturbed sites during project planning on a case-by-case basis. Suggested levels of minimum effective cover are: for EHR of 4-5, 40 percent; for EHR of 6-8, 50 percent; for EHR of 9-10, 60 percent; for EHR of 11-13, 70 percent. These suggested levels are adopted as the LRMP ground cover standard for the Keddie Ridge Hazardous Fuels Reduction Project.
- To avoid land base productivity loss due to soil compaction, dedicate no more than 15 percent of timber stands to landings and permanent skid trails. Permanent landings and skid trails do not exist within the project area and the Keddie Ridge Project does not propose such permanent features.

Sierra Nevada Forest Plan Amendment (SNFPA) Record of Decision (ROD)

The SNFPA ROD (USDA 2004b) amends the Plumas National Forest LRMP and includes a standard and guideline for down wood and snags:

- Determine retention levels of down woody material on an individual project basis. Within westside vegetation types, generally retain an average over the treatment unit of 10-15 tons of large wood per acre. Within eastside vegetation types, generally retain an average of three large down logs per acre. For the Keddie Ridge Project, the retention level of down woody material is 10-15 tons of large wood per acre (refer to the Affected Environment or Existing Condition sections below).

Direction Relevant to the Project as it Affects Water Resources

Clean Water Act of 1948 (as amended in 1972 and 1987)

The Clean Water Act of 1948 establishes as federal policy the control of both point and non-point pollution and assigns to the states the primary responsibility for control of water pollution.

State Water Quality Management Plan

Non-point source pollution on Plumas National Forest is managed through the water quality management program contained in *Water Quality Management for Forest System Lands in California* (USDA 2000). This document describes Forest Service practices and procedures for protection of water quality and also contains the 1981 Management Agency Agreement (MAA) between the California State Water Resources Control Board and the USDA, Forest Service. The State Board has designated the Forest Service as the management agency for all activities on National Forest lands and the MAA constitutes the basis of regional waivers for non-point source pollution. The Forest Service water quality protection program relies on implementation of prescribed best management practices (BMPs). Best management practices are procedures and techniques that are incorporated in project actions and have been determined by the State to be the most effective, practicable means of preventing or reducing the amount of pollution generated by nonpoint sources to a level compatible with water quality goals. BMPs applicable to the Keddie Ridge Project are presented in appendix H of this DEIS.

Section 303(d) of the Clean Water Act

This section requires the identification of water bodies that do not meet, or are not expected to meet, water quality standards or are considered impaired. The list of affected water bodies, and associated pollutants or stressors, is provided by the State Water Resources Control Board and approved by the United States Environmental Protection Agency. The most current list available is the 2006 303(d) list (SWRCB 2006). No water bodies on this list are located within the Keddie Ridge Project area. However, principal watersheds (at the HUC-5 scale) affected by the project are Lights Creek, Lower Indian Creek and Wolf Creek—these watersheds comprise a sizable portion of the East Branch North Fork Feather River watershed. The North Fork Feather River is included on the 2006 303(d) list for mercury and water temperature impairments. The Keddie Ridge Project would not affect legacy deposits or concentrations of mercury in the North Fork Feather River. The 303(d) list describes hydropower modifications and flow regulation/modification as the potential sources for water temperature impairments.

Beneficial Uses identified by the CA Regional Water Quality Control Board (Central Valley Region)

Beneficial uses are defined under California State law in order to protect against degradation of water resources and to meet state water quality objectives. The Forest Service is required to protect and enhance existing and potential beneficial uses (CRWQCB 1998). Beneficial uses of surface water bodies that may be affected by activities on the Forest are listed in Chapter 2 of the Central Valley Region's Water Quality Control Plan (commonly referred to as the "Basin Plan") for the Sacramento and San Joaquin River basins (CRWQCB 1998) and are described below for the Keddie Ridge Project area.

California Regional Water Quality Control Board Conditional Waiver of Waste Discharge

In January of 2003, the Regional Water Quality Control Board (RWQCB)—Central Valley Region adopted Resolution No. R5-2003-005 that provides for a conditional waiver of the requirement to file a report of waste discharge and obtain waste discharge requirements for timber harvest activities on National Forest System lands within the Central Valley Region. Additional provisions were added in the 2005 Resolution No. R5-2005-0052. This project complies with the Clean Water Act through use of "Best Management Practices" designed to minimize or prevent the discharge of both point and non-point source pollutants from National Forest System roads, developments, and activities. Prior to initiation of any of the Keddie Ridge Project action alternatives, the Plumas National Forest would comply with RWQCB permit requirements per Resolution R5-2005-0052.

The Sierra Nevada Forest Plan Amendment (SNFPA) Record of Decision (ROD)

Appendix E of the SNFPA ROD (USDA 2004b) describes management direction applicable to the Herger-Feinstein Quincy Library Group (HFQLG) Pilot Project area. The ROD directs that Scientific Analysis Team (SAT) Guidelines (USDA 1999b) be applied to vegetation management projects in the Pilot Project area per the HFQLG FEIS and ROD (USDA 1999a,b). No standards and guidelines specific to riparian areas, hydrology, or water resources are presented in Appendix E of the SNFPA ROD.

Herger – Feinstein Quincy Library Group (HFQLG) Forest Recovery Final Environmental Impact Statement (FEIS) and Record of Decision (ROD)

The HFQLG ROD changed direction in the Plumas NF LRMP by requiring application of specific SAT guidelines for riparian management. These SAT guidelines include:

- Application of the following minimum buffer widths for riparian protection and delineation of riparian habitat conservation areas (RHCAs): 300 feet for perennial, fish-bearing streams and lakes; 150 feet for perennial, non fish-bearing streams, ponds and wetlands greater than 1 acre, and lakes; and 100 feet for intermittent and ephemeral streams and wetlands less than 1 acre.
- Prohibition of scheduled timber harvest in RHCAs except for salvage harvest or to meet SAT guidelines for resource management objectives.
- Management of fire and fuel treatments to meet resource management objectives and minimize disturbance of riparian ground cover and vegetation.

The SAT guidelines include ten riparian management objectives (RMOs) for RHCAs. To describe how this project's proposed timber harvest and fire and fuel treatments meet these objectives, an RMO analysis is provided in appendix E of this DEIS.

Plumas National Forest Land and Resource Management Plan (PNF LRMP)

Forest Plan standards and guidelines provide the relevant substantive standards to comply with NFMA. The 1988 LRMP (USDA 1988) establishes standards and guidelines for protection and maintenance of Forest watersheds, water quality, and water supply, including:

- Implementation of BMPs.
- Establishment of Streamside Management Zones (SMZs) per guidelines in Appendix M of the LRMP. These guidelines were mostly replaced by the SAT guidelines, RHCA width requirements mandated by the HFQLG ROD. However, ephemeral channels without evidence of annual scour and deposition are not addressed by the SAT guideline buffer widths. Therefore, SMZ widths defined in Appendix M of the LRMP are applied to these channels. Recommended SMZ widths for these ephemeral swales range from 0 to 50 feet, depending upon the stability of the swale channel and sideslope.

An SMZ plan is necessary for any activities that will occur within an SMZ, including a description of vegetation management objectives, needed erosion control measures, and an analysis of SMZ areas with over-steepened slopes or very high EHR. The SMZ plan for this project is included in appendix H of this DEIS.

Effects Analysis Methodology

Cumulative Watershed Effects analysis methods and assumptions

There are numerous methods for assessing the effects of land use activities on the landscape (USDA 1988, Berg 1996, Reid 1998). For the purpose of this CWE analysis, the effects of past, present, and reasonably foreseeable future actions were assessed using the Region Five Cumulative Off-site Watershed Effects Analysis (USDA 1988). Under this approach, the effects of land management activities were evaluated on the basis of Equivalent Roaded Acres (ERA). These ERA values serve as a "common currency" to describe effects from a wide range of management activities. The wide use of this model in Region 5 allows for comparisons among projects across both space and time.

Within each subwatershed in the watershed assessment area, past management activities were analyzed to account for the cumulative amount of land disturbance that has occurred within each subwatershed. The area of land manipulated by each past management activity was converted to a theoretical area of road surface, resulting in a measure of ERA. Numeric disturbance coefficients were used to convert these management effects to ERA effects in terms of the pattern and timing of surface runoff. Coefficients vary by management activity, silvicultural prescription, site preparation methods, type of equipment utilized, and fireline intensity (refer to Appendix D – Cumulative Off-site Watershed Effects Analysis Methodology of the Hydrology and Soils Specialist Report).

Dividing the total ERA by the size of the watershed yields the percent of the watershed in a hypothetically roaded condition. ERA model values are used to track general changes to hydrologic function of watersheds in terms of alteration of surface runoff patterns and timing. In this way, ERA values can serve as an index to assess effects on downstream water quality. An increase in ERA for a watershed could result in detrimental changes to sedimentation rates and stream channel condition and subsequently have effects on downstream water quality and beneficial uses.

As the amount of anthropogenic landscape manipulation increases within a watershed, the susceptibility of that watershed to cumulative watershed effects (CWE) increases. There is a point where additive or synergistic effects of the land use activities will cause the watershed to become highly susceptible to CWE. Natural watershed sensitivity is an estimation of a watershed's natural ability to absorb land use impacts without increasing CWE to unacceptably high levels. Watersheds and their associated stream systems can tolerate some level of land disturbance, but there is a point at which land disturbances begin to substantially affect downstream channel stability and water quality. Upper limits of watershed "tolerance" to land use are estimated for the ERA model, this upper limit is called the threshold of concern (TOC).

For the ERA model analysis, the TOC for each subwatershed is expressed in terms of the percent of the area in a hypothetically roaded condition. The TOC does not represent the exact point at which cumulative watershed effects will occur. Rather, it serves as a "yellow flag" indicator of increasing susceptibility for significant adverse cumulative effects occurring within a watershed. As ERA disturbances approach the TOC, there is an increased risk that soil hydrologic function, downstream water quality and beneficial uses would be impaired. For example, stream channels can deteriorate to the extent that riparian and meadowland areas become severely damaged.

A closer look at the activities planned within an analyzed watershed would be important where ERA values exceed or are approaching the TOC. The TOC for this project was developed by considering the natural sensitivity of the Keddie Ridge Project subwatersheds and the sensitivity of downstream beneficial uses to changes in watershed hydrologic function. Watershed sensitivity analyses for the HFQLG Pilot Project watersheds were reported in Appendix N the HFQLG Forest Recovery Act Final Environmental Impact Statemen t (USDA 1999a). The majority of HFQLG Pilot Project watersheds applicable to this project received moderate sensitivity ratings. Examples given in the R5 Soil and Water Conservation Handbook estimate the TOC for watersheds of moderate sensitivity to be 15 to 16 percent. For this project, the TOC is conservatively estimated to be 12 percent of the watershed area. For additional information, refer to the “Watershed Sensitivity” section below.

Assumptions: In calculating the ERA contribution by the proposed harvest activities, all areas of the treatment units were assumed treatable. For example, no compensations were made for rock outcrops, roaded areas, or small-scale slope limitations that would restrict harvest activities. In most cases, such site-specific information was not available. Coefficients were applied to similar activities regardless of soil type, slope conditions, season of operation, or specific equipment characteristics. In calculating ERA contributions due to roads, all roads were considered equally, regardless of surface material (pavement, gravel, or native soil surface). Acres of roads were calculated by assuming that temporary and unclassified roads are 20 feet wide, and all other roads are 25 feet wide. The linear recovery curve (Figure 13) used in this analysis is not necessarily reflective of recovery patterns on the ground. Linear recovery models tend to under-predict effects in the very early stages of recovery, and over-predict effects in later stages of disturbance recovery.

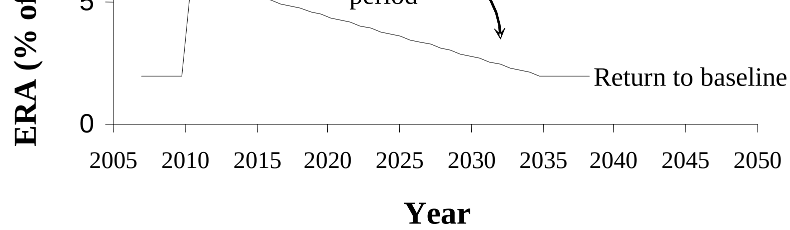

Figure 13. Conceptual Disturbance and Recovery Model for a Harvest Activity.

Soil Assessment Analysis Methods and Assumptions

In the summer of 2007, the soil and hydrology field crew, under the direction of the District soil scientist, assessed soil productivity measures for all soil types in the proposed treatment units. Though not all units were quantitatively surveyed, site visits were made to all units to verify existing conditions and confirm that the survey units chosen as surrogates had similar soil texture, cover, and condition. The fuel treatment units and area thinning units were sampled using similar methods. Due to the potential ground disturbance, units proposed for mechanical harvest treatment were given the highest priority for soil assessment. Soil-related information was collected in 29 of the proposed Defensible Fuel Profile Zone (DFPZ) units and three of the area thinning units described in the proposed action. The fuel treatment units were sampled more intensively because the proposed treatments are expected to affect a larger proportion of each treatment unit and there are substantially more of them. The proposed treatments in the area thinning units are expected to be more dispersed. When implementing group selection, the typical management unit or stand in which growth is regulated consists of an aggregation of groups, not individual groups. To assess soil conditions at an appropriate scale for group selection management, soil surveys were conducted at the scale of the area thinning unit.

The R5 Soil Quality Analysis Handbook states that a 10 percent reduction in total soil porosity corresponds to a threshold soil bulk density that indicates detrimental soil compaction (USDA 1995). To assess for detrimental soil compaction, the “spade method” was used which consists of measuring compaction from the resistance felt from sticking a spade shovel at the transect point into the ground. Per Exhibit 01 of the R5 Soil Quality Analysis Handbook, soil bulk density samples were collected and analyzed on soils similar to soils found in the project area to calibrate the spade method and assure that the person performing the test properly correlated the resistance felt with threshold soil bulk densities. Subsequently, a 12-16 inch deep and 6-12 inch wide hole was excavated with the spade to assess whether detrimental compaction exists based upon field indicators of soil compaction.

Watershed and Soil Indicators

Direct and Indirect Effects of DFPZ and WUI Fuels Reduction Treatments

Soil productivity indicators consist of the soil properties required for analysis by the PNF LRMP and the R5 Soil Management Handbook: soil cover, soil porosity, and soil organic matter. Organic matter levels are used as indicators of soil productivity. Effective soil cover is used to evaluate the potential for accelerated erosion. Effective soil cover consists of material that impedes rain drop impact and overland flow of water, including organic residues 0.5-inch thick, exposed roots, stumps, surface gravels more than 0.75 inch, and living vegetation. Minimum effective ground cover for the Keddie Ridge Project is prescribed at 40, 50, 60, or 70 percent on areas with maximum Erosion Hazard Ratings of low, moderate, high, and very high, respectively.

A 10 percent reduction in total soil porosity corresponds to a threshold soil bulk density that indicates detrimental soil compaction. Reductions in soil porosity correspond with increases in soil bulk density. The extent of detrimental soil disturbance shall not be of a size or pattern that would result in a significant change in production potential for the activity area. Organic matter losses are assessed by measuring the surface fine organic matter and large woody material. The threshold value for surface fine organic matter is at least 50 percent cover over the activity area, and includes plant litter, duff, and woody material less than 3 inches in diameter. Desirable large woody material is composed of logs at least 20 inches in diameter and 10 feet long. The recommended threshold for logs is 5 logs per acre (which could range from 3 to 10 tons per acre depending on decay class and size), representing the range of decomposition classes. Levels of fine organic matter and large woody material may be reduced to meet fuel management objectives, except when needed for essential erosion control.

Water quality indicators include potential for increased sedimentation rates. The effectiveness rate from Best Management Practice (BMP) monitoring informs this indicator.

Cumulative Effects Analysis

As described above, for the cumulative watershed effects model, past management activities were analyzed to account for the cumulative amount of land disturbance that has occurred within each subwatershed. The area of land manipulated by each past management activity was converted to Equivalent Roaded Acre values and the total ERA, expressed as a percentage of subwatershed area, was compared to the threshold of concern. Subwatersheds that exceed or are approaching the TOC are indicated to be at a higher risk of cumulative detrimental effects to downstream beneficial uses. A closer look at the activities proposed within those subwatersheds is necessary.

Table 67. Summary of Environmental Indicators and Measures Examined in this Assessment

Key ecosystem element	Environmental indicators	Variable Assessed
Water Quality	Chronic sedimentation, accelerated hillslope erosion	BMP effectiveness rate, Equivalent roaded acres (ERA), threshold of concern (TOC)
Soil Productivity	Soil loss Detrimental compaction Organic matter losses	Effective soil cover Soil porosity as indicated by soil bulk density, large down wood, surface fine organic matter

In order to understand the contribution of past actions to the cumulative soil productivity effects of the Proposed action and alternatives, this analysis relies on current soil conditions as a proxy for the impacts of past actions. This is because existing soil conditions reflect the aggregate impact of prior human actions and natural events that have affected the environment and might contribute to cumulative effects. Water quality and soil productivity variables are summarized in Table 67.

This cumulative soil effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to. Current soil conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual soil impacts would be nearly impossible. Second, focusing on individual actions would be less accurate than looking at existing soil conditions, because there is limited information on the soil impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focus on the soil impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we capture the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.

Affected Environment

Soils

Soil Assessment Area

The soil assessment area (Figure 14) consists of the defensible fuel profile zone (DFPZ) fuel treatment units, area thinning units, and noxious weed treatment units described in the Proposed action. Note that Figure 14 shows the soil assessment area boundary for reference.

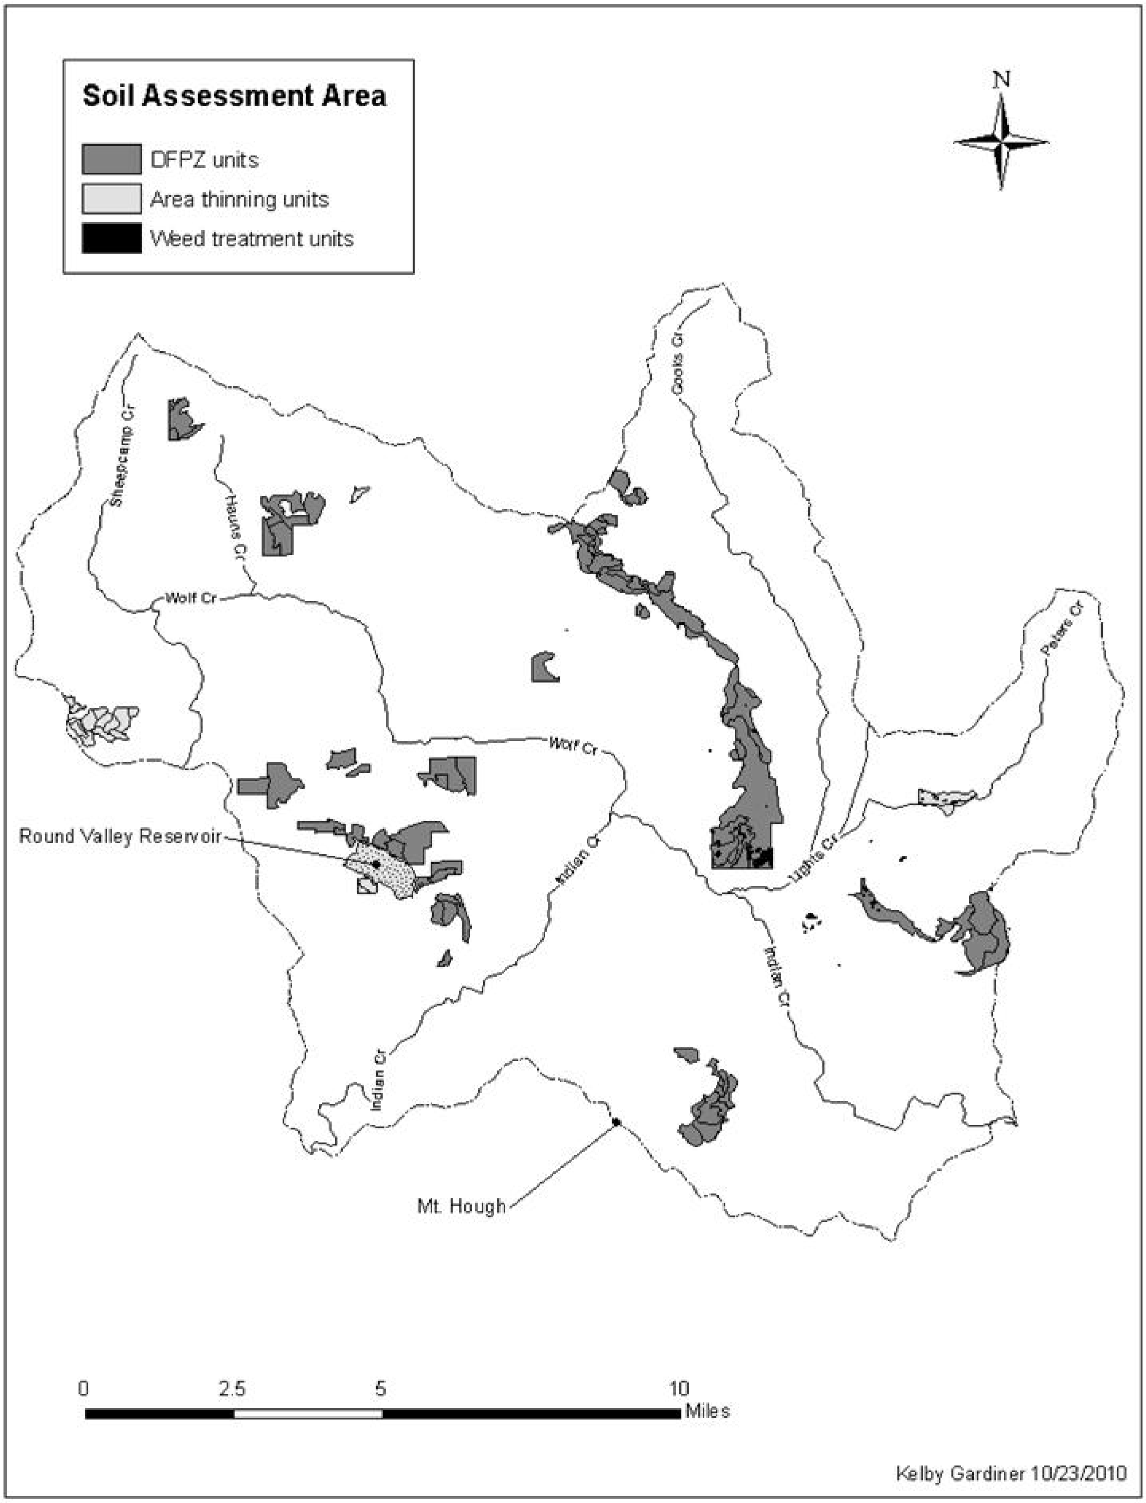

Figure 14. Soil Assessment Area

Soil Condition

Forest productivity in the assessment area ranges from low productivity to non-productive sites (USDA 1988). Forest survey site class (FSSC) is a measure of site productivity in cubic feet of wood per acre per year. Site class 1 is the most productive, while FSSC 7 is the least. Site class 7 lands are considered non-productive, and occur in 148 acres of treatment units along ridgetops and steep rocky slopes. Both site class 5 and 6 lands are interpreted as having low productivity (USDA 1999a), while site class 4 is slightly more productive. Round Valley reservoir and the Hauns Creek area possess most of the site class 4 lands, which make up 21 percent of treatment units. Site class 5 lands are found throughout the project area and make up roughly 24 percent of treatment units. The majority (53 percent) of soils found within the assessment area are site class 6 lands. Site class 7 lands account for 2 percent of treatment units, most of which occur in the Peters Creek area.

The maximum erosion hazard ranges from moderate to very high in the soil assessment area (Table 68). This erosion hazard rating (EHR) predicts the potential for sheet, rill, and gully erosion under existing conditions if vegetation and litter are removed. Moderate EHR exists on 2,376 acres of DFPZ and area thinning units, high EHR makes up 3,418 acres, while 148 acres are rated as having a very high EHR.

Soils in the project area are derived from both igneous and metamorphic parent material. Igneous rock can be formed in two ways; below ground as an intrusive or plutonic occurrence, or at the earth's surface as an extrusive or volcanic formation. Metamorphic parent material was igneous, metamorphic, or sedimentary rock that has been subjected to extreme heat and pressure causing physical and or chemical changes.

Parent material in the western portion of the project area, near the community of Canyon Dam, is comprised of andesite, schist, greenstone, peridotite, and andesitic tuff breccias. These geologic occurrences weather to form soils generally classified as loam with several site dependent modifiers including; cobbly, gravelly, sandy, silty or clay loam.

Table 68. Soil Productivity Results from Field Surveys

Geographic area	Average percent soil cover	Average areal extent of detrimental compaction	Average number of down logs per acre	Average percent cover of fine organic matter	Unit Number(s)	Erosion Hazard Rating
Taylorsville/ Peters Creek	84	20	16	81	89 & 93	M, H, & VH
Keddie Ridge	95	15	20	74	2, 4, 9,12, 14, 15, 18, 20-28, 60, 68, 69, & 83	M, H, & VH
Canyon Dam/ Hauns Creek	96	13	40	52	10, 11, 56-58	M & H
Round Valley Reservoir	95	15	28	91	74, 78, 79, 82, & 85	M & H
China Grade	92	0	24	87	98 & 106	M & H

Effective Soil Cover—LRMP Standard

Effective soil cover is necessary to prevent accelerated soil erosion. Soil cover ranges from 77 to 100 percent for the surveyed units. PNFLRMP standards and guidelines for effective ground cover vary by the soil erosion hazard rating. Effective ground cover should be maintained at 60 percent for soils with a high erosion hazard rating (EHR), and 50 percent for soils with a moderate EHR.

Soil Compaction—LRMP Standard and Region 5 Guidance

The R5 Soil Management Handbook provides a soil porosity threshold to determine the intensity of compaction that is deemed detrimental. The extent of detrimental soil compaction shall not be of a size or pattern that would result in a significant change in production potential for the activity area. The spatial extent of detrimental compaction that would cause a significant reduction in productive capacity would likely vary by local factors such as soil type and climate. Table 68 summarizes the average existing spatial extent of detrimental compaction measured during field evaluations. The area of detrimentally compacted ground is primarily occupied by skid trails and landings, although not all skids and landings were deemed compacted.

Down Woody Material—LRMP Standard and Region 5 Guidance

The applicable standard for large down wood is in the PNF LRMP as amended, which states that down woody material retention levels should be determined on an individual project basis. For the Keddie Ridge Project, 10 to 15 tons per acre of the largest down logs, where they exist, will be retained. The Region 5 guidance provides a threshold for large woody material, recommending retention of 5 logs per acre (3 to 10 tons per acre) representing the range of decomposition classes. The existing average number of large down logs per acre in the surveyed units ranged from 23 to 32.

Fine Organic Matter—Region 5 Guidance

The Region 5 guidance provides a threshold for surface fine organic matter, recommending retention of 50 percent cover in all stands. Organic cover helps maintain site fertility and prevent soil loss from erosion. Fine organic matter consists of plant litter, duff, and woody material less than three inches in diameter. Average cover of fine organic matter ranged from 61 to 82 percent in surveyed units Table 68.

Watershed

Watershed Assessment Area

The area defined for the watershed assessment encompasses 12 sub-watersheds, which are contained in 10 HUC 6 watersheds. The Wolf Creek, Lights Creek, and Indian Creek systems converge in the Indian Valley basin and flow southwest, draining the assessment area (Figure 15). Indian Creek joins Spanish Creek at the boundary of the assessment area to form the East Branch North Fork Feather River.

Watershed Condition

The existing conditions reflect the aggregate impact of prior human actions and natural events such as wildfire that have affected the environment and might contribute to cumulative effects. The ERA model attempts to accurately account for the cumulative effects of past, present, and reasonably foreseeable actions and combine such effects into a single aggregate ERA value that represents the current condition of each subwatershed. The following discussion does not attempt to recount all possible factors that contributed to the cumulative watershed effects (CWE) ERA analysis or list all human or natural impacts that occurred within the soil assessment area during the analysis timeframe (35 years). Instead, it simply focuses on some of the major contributing factors used to calculate the current condition ERA values and assess future effects. The current conditions in the analysis subwatersheds have been impacted by many actions over the last century— specifically mining, grazing, and timber harvesting.

Tractor logging during the 20th century has left noticeable effects on the composition of the timber stands remaining today, including effects on tree species composition, age, and diameter classes. From 1980 to 2010, scheduled timber harvests and associated activities on NFS lands treated approximately 35,000 acres in the analysis subwatersheds. In some cases, individual stands were treated multiple times, so the actual number of affected acres is slightly less. Silvicultural prescriptions included clear cutting, overstory removal, group selection, sanitation, shelterwood, and area thinning, as well as associated activity fuel burning. Between 1997 and 2010, proposed harvest activities on private lands called for harvests on approximately 9,670 acres of timberland in the analysis subwatersheds.

There are 9,399 acres in the analysis subwatersheds that were burned in wildland fires between 1964 and 2010. Large wildfires (the Moonlight Fire burned 4,994 acres within the Keddie Ridge watershed assessment area) have resulted in severe impacts on soil productivity and subwatershed condition in these areas, but conditions will continue to improve as soil cover and organic matter accumulate.

Historically, livestock grazing occurred throughout a large portion of the watershed assessment area, especially on the private land that makes up the majority (8,400 acres) of Indian Valley. Today, there are still portions of two allotments on National Forest System lands within the watershed assessment area—Taylor Lake and the Lights Creek allotments—though the majority of grazing impacts to date are most visible along the banks of Lights and Indian Creeks in the valley bottom private lands.

Historic logging, mining, and grazing have also influenced the hydrologic and vegetative characteristics of the analysis watersheds. Such historic legacy effects are common to many of California's forested watersheds (Cafferata et al. 2007). More recent forest activities, including fire suppression and development of the transportation system, continue to affect the watershed conditions in this area. Unpaved roads are often considered the primary source of sediment to stream channels (MacDonald and Coe 2007).

Generally, recreational activities occur throughout the entire Keddie Ridge Project area, with concentrated use around the communities of Taylorsville and Greenville. Round Valley Reservoir, the municipal water supply for Greenville, is a popular boating and fishing destination. Dispersed recreational impacts of undeveloped camping areas, firewood cutting, user-created roads and trails are evident. Off-highway vehicle (OHV) use may contribute to compacted soil conditions where these activities occur. The locations of many user-created features have recently come to light under the national OHV route designation process. The selection of alternative 5 of the Travel Management EIS allows many of these routes to be incorporated into the ERA assessment for future projects, with actions planned to improve and maintain selected trails (USDA 2010b). Other recreational activities, such as Christmas tree cutting, hiking and hunting, have negligible effects on the soils or ERA assessment.

Data obtained from the California Department of Pesticide Regulation identified approximately 1,200 pounds of glyphosate (isopropylamine salt) applied to 345 acres in the watershed assessment area (at varying application rates) between 2004 and 2008 (CDPR 2009). There was no reported use of aminopyralid within the Keddie Ridge watershed assessment area.

Beneficial Uses

Existing beneficial uses of surface waters in the Keddie Ridge Project area are found in the Central Valley Region Water Quality Control Plan (CRWQCB 2004). The Keddie Ridge Project drains to the North Fork Feather River, for which existing beneficial uses include municipal and domestic water supply, hydropower generation, recreation, freshwater habitat, habitat suitable for fish reproduction and early development, and wildlife habitat.

Forest Vegetation

A mixed conifer forest type dominates the watershed assessment area, though several pine plantations and oak woodlands are established in burned areas and clear cut units. Much of the existing forest contains dense ladder fuels and fuel loading up to 100 tons per acre. High fuel loads occur in stands that experienced deadfall of mortality due to a region-wide drought in the late 1980s. High densities of small trees and high fuel loads contribute to high accumulations of ladder fuels and canopy fuels. These fuel conditions are conducive to crown fire initiation and propagation, and increased potential for stand-replacing high-severity fire events. Conditions within riparian habitat conservation areas (RHCAs) are similar to those described above. This includes conifer encroachment within the RHCAs, which has lead to a decline in riparian species that cannot tolerate a completely shaded environment. The high density of small trees makes many RHCAs within the Keddie Ridge Project area vulnerable to the effects of severe wildfire because drainages can rapidly funnel hot air upslope, contributing to fire spread. For example, thousands of acres of RHCAs within the Stream Fire of 2001 and the Moonlight Fire of 2007 were severely burned.

Stream condition

According to the PNF corporate GIS stream layer, there are nearly a 1,000 miles of stream in the Keddie Ridge watershed assessment area (Table 69); approximately 53 percent of the stream miles are ephemeral, 32 percent are intermittent, and 15 percent are perennial. Ephemeral and intermittent streams are seasonal—they run water during some portion of the year but are typically dry by late summer. Ephemeral streams only flow in response to storm events or snowmelt, and do not necessarily flow every year. Intermittent streams are seasonally connected to the surrounding water table and may flow during all but the driest months, whereas perennial streams typically flow year round. Streams are further classified by their slope—response reaches have low-gradient (less than three percent slope) alluvial conditions. The morphology of response channels reflects depositional processes associated with flowing water. Transport reaches have higher gradient (3 to 12 percent slope), non-alluvial conditions and the morphology of transport channels is generally resilient to change.

As mentioned in the "watershed condition" section above, historic land management activities have noticeably impacted the landscape. This is evident in many of the stream channels that drain the Keddie Ridge Project area. The headwaters of Wolf Creek are home to Calgom mine, where over 80 acres of hydraulic mining has occurred. Active placer mining claims are also present along much of Wolf Creek between the community of Canyon Dam and Greenville. This stretch of creek is closely paralleled by Highway 89 on the north and a railway on the south, confining stream flows to the active channel and contributing above normal amounts of sediment to the system during and after precipitation events. Riparian vegetation is well established and has excellent diversity: willow, black cottonwood, big-leaf maple, red-osier dogwood, and alder are all abundant with the occasional aspen stands present as well. Hauns and Sheepcamp Creeks flow through a considerable amount of private land in a southerly direction and are tributary to Wolf Creek. A significant amount of historic private timber harvest and road construction has occurred in this area, greatly contributing to the cumulative watershed effects of Wolf Creek. It is noteworthy to mention that the Mt. Hough Ranger District completed a multi-year stream restoration project on Wolf Creek in 2010. Over a quarter mile of vertical stream banks were laid back to form a new flood plain which was stabilized with erosion cloth and native vegetation. Log and rock veins were placed in the active channel to encourage deposition of bedload material mobilized by the aforementioned actions.

The portion of the Lights Creek watershed that is considered in this analysis encompasses Cooks Creek, Peters Creek, and the lower portion of Lights Creek that flows through Indian Valley—approximately one quarter of the entire Keddie Ridge watershed assessment area. The 2007 Moonlight Fire burned just over 900 acres of RHCA in the Cooks and Peters Creek subwatersheds—most of which occurred at the headwaters of these basins. Field surveys by district watershed staff show that channels are well armored by rock and large woody debris, with vigorous growth of riparian and upland vegetation present in the years following the fire. Improved effectiveness of stream buffers to filter sediment is apparent. Willow, big-leaf maple, and alder are the dominant riparian species present in the eastern portion of the Keddie Ridge Project. Aspen are established in the headwaters of Peters Creek and have benefited from the Moonlight Fire, where the fire has consumed encroaching conifers, consequently opening the canopy and improving the potential for aspen to further colonize. The Lucky S mine, a historic mining area that was thoroughly exploited for gold, is located in the headwaters of Peters Creek. Lower Peters Creek is the site of a hydropower special use permit maintained by a local resident, but operations generally cease in late summer when stream flow begins to subsurface.

Tributaries in the Lower Indian Creek watershed are comparable to those of the Lights Creek drainage system. Riparian vegetation is composed of willow, big-leaf maple and alder, but many of the steep ephemeral and intermittent streams lack vegetation due to the extremely rocky, well-drained soil, and the dense overstory canopy of confers. Indian Creek merges with the two previously mentioned drainages, Lights and Wolf Creeks, and continues to flow in a westerly direction through the project area as a low gradient response reach. As Indian Creek exits Indian Valley, downstream of the community of Crescent Mills near the Arlington Bridge, its gradient begins to increase and it is considered a transport reach. Geologic historian Cordell Durrell speculates that Indian Valley was once inundated in nearly a thousand feet of water. Arlington Bridge is thought to be the site of the outlet of the, now completely sediment filled, lake (Durrell 1988).

There are over 650 miles of existing roads within the watershed assessment area. Although the road network is generally in good condition, a number of poorly located roads contribute to substantial resource damage. These roads generally run parallel to and extremely close to stream channels. Rainfall can run off of road surfaces, carrying sediment into the stream network thus reducing water quality. Culverts can prevent fish from accessing upstream habitat by creating depth, leap, and velocity barriers.

Thousands of Canada thistles (*Cirsium arvense*) are present within the Keddie Ridge Project area. Many of these are located in riparian habitat conservation areas (RHCAs). Canada thistle is a noxious, invasive weed that can spread rapidly and potentially displace native plant species. The presence of Canada thistle is a high management concern due to its distribution and abundance within the Keddie Ridge Project area. As a noxious weed, it poses a threat to biological plant diversity in RHCAs. Affected streams include: South Fork Foreman Ravine, Cooks Creek, Peters Creek, and several unnamed seasonally flowing tributary channels.

Table 69. Miles of Stream Type and Stream Density in the Watershed Assessment Area

Drainage system	Drainage area (ac)	Miles of stream by type			Total stream miles	Stream density[1] (mi per mi^2)
		Ephemeral	Intermittent	Perennial		
Lights	26,198	119	65	41	224	5.5
Lower Indian	32,883	175	115	40	330	6.4
Wolf	46,818	232	142	56	430	5.9
Total	105,899	526	322	137	984	5.9

[1]Stream density is determined as the miles of stream per square mile of drainage area. Drainage area is shown in acres to be consistent with other area representations in this document.

Watershed Sensitivity

Watershed sensitivity analyses for the HFQLG Pilot Project watersheds were reported in Appendix N the HFQLG Forest Recovery Act Final Environmental Impact Statement (USDA 1999a). The sensitivity ratings were based on the erosion potential, slope steepness, amount of alluvial channels, risk of rain-on-snow and/or thunderstorm events, and on revegetation potential. Of the 12 HFQLG Pilot Project watersheds applicable to this project, 10 received moderate sensitivity ratings. Based on these ratings, most subwatersheds analyzed in this assessment were considered to have moderate sensitivity and were assigned a “threshold of concern” (TOC) value of 12 percent of the subwatershed area. Lower Cooks Creek watershed is more susceptible to cumulative effects, with a TOC value of 10 percent based on road and channel conditions and a higher sensitivity rating. Peters Creek watershed has been only somewhat disturbed by land uses, has fewer steep slopes and a lower road density—all of which lead to a slightly higher TOC value of 14 percent.

Precipitation

The Keddie Ridge Project is situated at the northern edge of the Sierra Nevada, with the Lake Almanor basin marking the transition into the Cascade mountain range and the northwestern edge of the watershed assessment area for the proposed hazardous fuels reduction project. Average annual precipitation data from the Rattlesnake Hill weather station, located 5 miles west of Round Valley Reservoir at an elevation of 6,100 feet, averaged 37 inches of rain between 2004 and 2010 and is representative of the western side of the Keddie Ridge watershed assessment area. The Kettle Rock rain gauge, 18 miles east of Rattlesnake Hill, sits 7,800 feet above sea level at the eastern boundary of the watershed assessment area and reflects the rain shadow effect that the Sierra Nevada experiences. Over the same seven-year period (2004-2010), average annual precipitation was approximately 30 inches (DWR 2010).

Precipitation falls primarily as snow above 6,500 feet and as a combination of snow and rain below that elevation. The majority of annual rainfall is characteristic of the Mediterranean climate, with most precipitation occurring between October and May with isolated thunderstorms common during the summer months. Surface runoff depends upon the snowmelt regime, which normally extends into late spring and early summer.

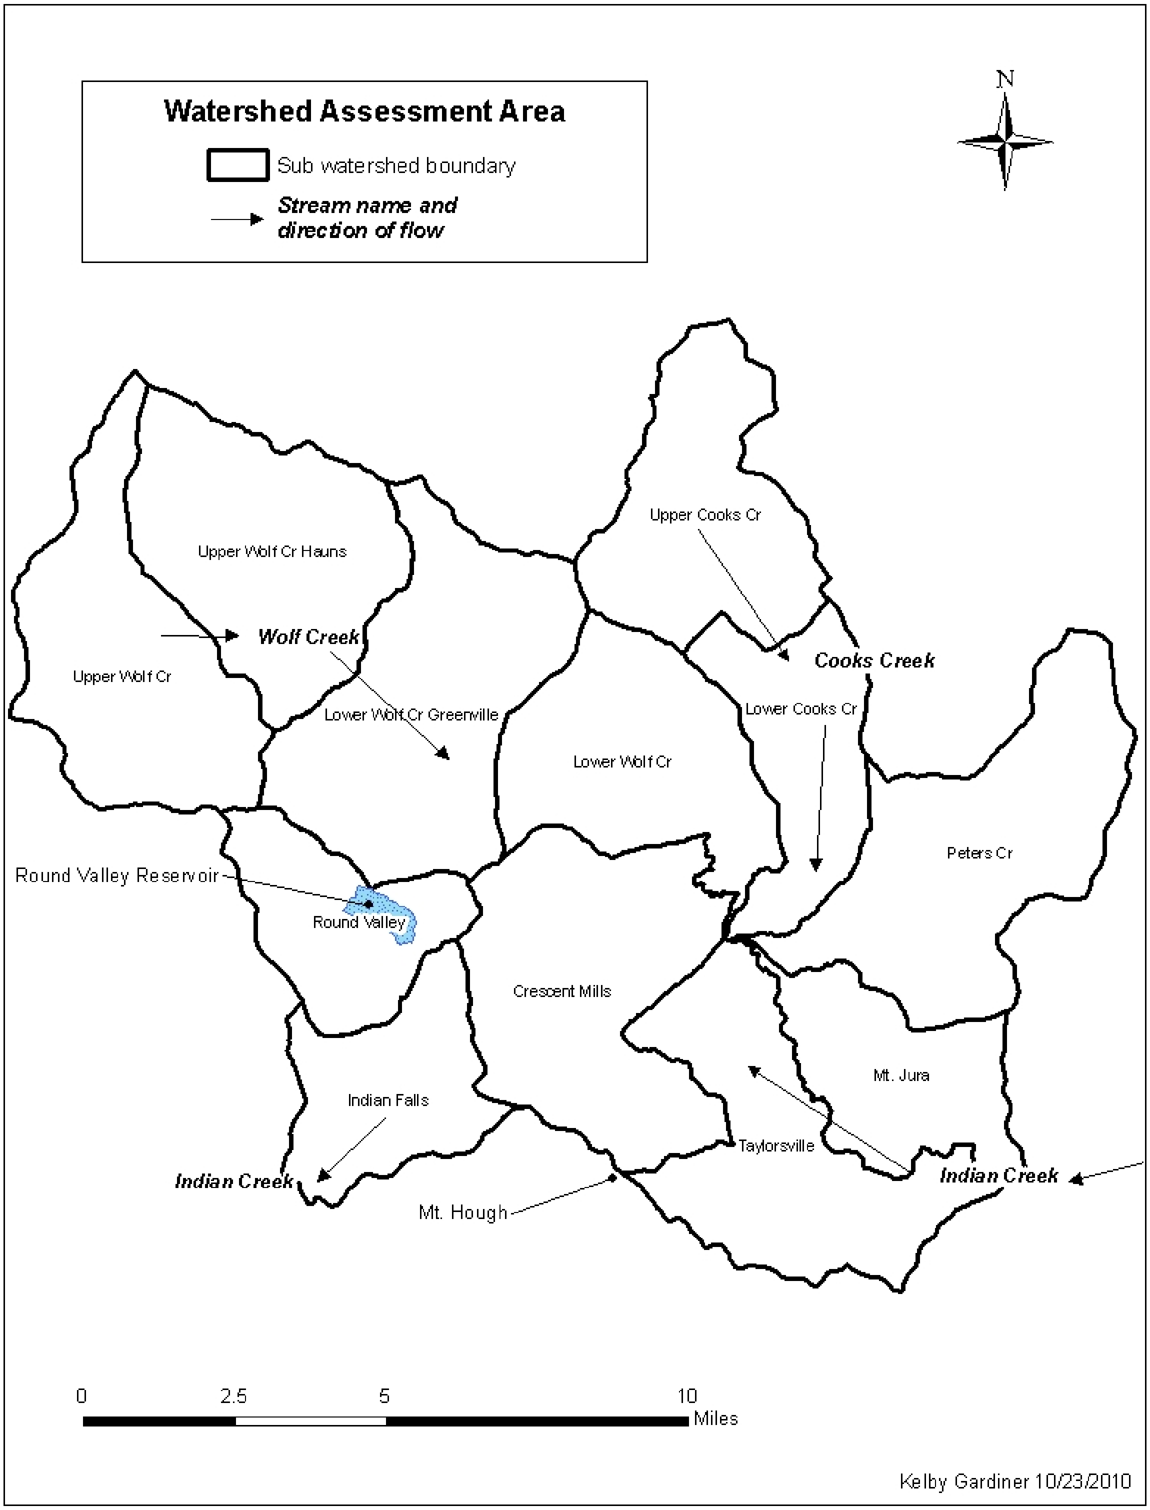

Figure 15. Watershed Assessment Area

Environmental Consequences

Design Criteria

Chapters 1 and 2 of the DEIS provide detailed information about the design criteria for each alternative. All mechanical harvest operations would adhere to standards and guidelines set forth in the timber sale administration handbook (Forest Service Handbook [FSH] 2409.15) and the best management practices as delineated in the "Water Quality Management for Forest System Lands in California: Best Management Practices" (USDA 2000). Timber sale contracts contain many standard provisions that help ensure protection of soil and water resources. These include provisions for an erosion control plan, road maintenance, and skid trail spacing.

Proposed management activities in RHCAs are expected to contribute to improving or maintaining watershed and aquatic habitat conditions described in the riparian management objectives (refer to Appendix C – RHCA Treatment; riparian management objectives (RMOs) of the Hydrology and Soils Specialist Report). RHCA widths are consistent with the Scientific Analysis Team (SAT) guidelines set forth in Appendix L of the HFQLG Final EIS. Where RHCAs would be treated, prescriptions and protection measures have been designed to address the RMOs. Where RHCAs would be mechanically treated, ground-based equipment would only be used on slopes less than 25 percent and on stable soils. To provide a buffer between streams and mechanically treated areas, an equipment exclusion zone would be established. The buffer width would vary by stream type and the steepness of the side slope, as shown in Table 70. For example, all mechanical equipment would be excluded from within 100 feet (horizontal) of perennial fish-bearing streams with sideslopes of 0 to 15 percent, and 150 feet from perennial fish-bearing streams with sideslopes between 15 and 25 percent. These streamside zones would serve as effective filter and absorptive zones for sediment originating from upslope treatment areas. Fuel reduction in these equipment-exclusion zones would be allowed and would be determined on a site-by-site case to protect the sensitive attributes associated with the riparian area.

Table 70. Equipment Restriction Zones and Burn Pile Restriction Zones in RHCAs

Stream Type	Equipment Restrictions by Slope Class			Burn pile restrictions by Slope Class[a]	
	0–15%	15–25%	>25%	0–15%	>15%
Perennial, fish bearing	100 ft	150 ft	No mechanical treatment	25 ft	40 ft
Perennial, no fish	50 ft	100 ft	No mechanical treatment	25 ft	40 ft
Intermittent	25 ft	50 ft	No mechanical treatment	15 ft	25 ft
Ephemeral	25 ft	25 ft	No mechanical treatment	15 ft	15 ft
Reservoirs/wetlands greater than 1 acre	50 ft	75 ft	No mechanical treatment	15 ft	25 ft

[a] Where feasible, burn piles would not be placed any closer to streams than the distances shown

Soil Analysis

This section is organized by the four soil indicator measures: effective soil cover, soil compaction, down woody material, and fine organic matter. Effects to each measure are first discussed for alternative B, the no action alternative, followed by a section titled, "Effects common to the action alternatives". In terms of the soil indicator measures, effects to each individual action alternative are very similar, the effective difference between action alternatives being the number of units and total acres to be treated. However, these differences would exist at small, localized scales and differences in effects to soil productivity, hydrologic function, and buffering capacity at the scale of the project area would be difficult to discern. Effects from the herbicide treatment are discussed separately above.

Effective soil cover—Alternative B

Direct Effects

Under the no action alternative, soil cover can be expected to increase as organic materials accumulate on the forest floor. Existing levels of soil cover are shown in Table 68. Soil cover ranges from 77 to 100 percent for the surveyed units and will likely develop increased cover under the this alternative.

Indirect Effects

As a result of increased soil cover, the risk of soil erosion may decline on forested hill slopes. Soil cover dissipates the energy of falling raindrops by intercepting them before they strike the soil surface. Reduced soil erosion would help retain soil nutrients and a favorable growth medium on site. The continued accumulation of organic matter on the forest floor would contribute to increased ground and surface fuel loads, which may lead to increased fire severity and intensity during a fire event.

Cumulative Effects

Due to fuel reduction treatments proposed for the action alternatives, the risk of a high-intensity wild fire occurring in the near future would be higher under alternative B. If soil cover were reduced to bare soil following a wildfire, the soil would be more susceptible to erosion. In addition, fire can create a non-wettable layer below the surface known as hydrophobicity (Everett et al. 1995). During a precipitation event, soil above the non-wettable layer can become saturated and erode downslope due to rill formation and raindrop splash. Immediately following a moderate-intensity wildfire, the affected stand would likely not meet the PNF LRMP standards for effective soil cover. However, within several months, a thin layer of needles dropped from scorched trees would likely increase surface cover of organic matter (Pannkuk and Robichaud 2003).This needlefall effect has been observed by district watershed staff following numerous recent fires including: Cold, Rich, and Moonlight.

Effective Soil Cover—Effects Common to the Action Alternatives

Direct Effects

Harvest operations may increase soil cover by adding activity fuels to the forest floor, but can also decrease cover due to organic displacement during yarding operations. Mastication would generally increase soil cover because materials are shredded and then broadcast into the unit away from the machine. Prescribed fire activities, including pile burning and underburning, would consume organic materials and reduce the amount of effective soil cover. Recent BMP evaluations demonstrate that prescribed fires on the Plumas National Forest are effective in terms of leaving sufficient soil cover after implementation (USDA 2009a). Pile burning would remove soil cover locally, and underburning is expected to occur under prescribed conditions that would not result in complete consumption of the duff and litter layers.

Beginning in 2001, effective soil cover has been monitored on HFQLG project units for both the pre- and post-project condition per the Monitoring Plan prescribed in the 1999 HFQLG FEIS. Post-project monitoring began in 2004. For the 75 sets of data for pre- and post-harvest units, large differences between silviculture methods are apparent as the 51 thinning units averaged approximately 80 percent soil cover post-project and the 24 group selection units averaged approximately 60 percent effective cover post-project (USDA 2010b).

Statistical analysis of the thinning and group selection data sets available in 2007 determined statistically significant ($P < 0.05$) differences between pre- and post-project soil cover condition. For the 39 thinned units, the 95 percent confidence level described a post-project reduction in the areal extent of soil cover ranging from 9 percent to 15 percent. Average existing effective cover for thinning units proposed by the Keddie Ridge Project ranges from 84 percent to 96 percent. Since existing effective cover exceeds 75 percent for all of the units proposed for thinning, even the higher end of the 95 percent confidence range for decrease in soil cover (a 15 percent decrease) would leave the units with sufficient cover to meet the project standard of 50-60 percent.

For the group selection units, the 2007 HFQLG soil monitoring data indicated a statistically significant and more dramatic reduction in post-project ground cover. The average decrease in the areal extent of effective ground cover was 48 percent, with a 95 percent confidence interval ranging from -36 percent to -62 percent (USDA 2008e). Group selection (GS) units would occur within thinning units so existing soil cover reported above is applicable for GS units. A 2008 letter from the three Supervisors of the HFQLG Forests describes management techniques to assure project compliance with soil standards (USDA 2008f). These techniques include utilization of post-logging slash and designation of skid trails in group selection units. These techniques would result in a decrease for soil cover in group selection units that is much less substantial than the 48 percent decrease (on average) observed in the 2007 HFQLG monitoring report.

Indirect Effects

Increases in effective soil cover due to mastication or other operations would further reduce the risk of erosion by providing a physical buffer against wind and rain displacement of soil. A reduction in effective soil cover would increase the risk of erosion in affected areas. The amount and type of erosion depends on the character of the area. For example, patches of forest floor or other cover material across a large area would be more effective at intercepting surface water than large areas devoid of cover. The effect of short-term reductions in soil cover for action alternatives would generally be well distributed across treated units. Concentrated removal of soil cover is most likely to occur in areas such as landings, skid trails, temporary roads, and equipment tracks. Soil erosion will be minimized by the installation of erosion control structures (cross ditches and waterbars) which are standard timber sale contract practices.

After the initial reduction in effective soil cover due to mechanical treatments, effective soil cover would increase over the years due to needle cast and leaves falling from coniferous and deciduous trees that remain. Local reductions in soil cover may have local effects on soil temperature. Larger reductions may result in greater temperature extremes in the soil. Removal of canopy cover may result in increased temperatures at the forest floor as well as reduced moisture content of forest floor materials (Erickson et al. 1985).

Cumulative Effects

The treatments proposed in the action alternatives are generally expected to reduce effective soil cover, with the exception of the mastication treatment. The cumulative effects of the proposed activities, when considered with the past, present, and future activities, are expected to result in soil cover conditions that remain in compliance with the PNFLRMP standards. A reduction in ground cover would likely be short lived if nearby overstory trees remain intact. Over time, litter from trees and shrubs would contribute to the development of effective ground cover in bare areas. Due to proposed fuel reduction treatments proposed, the risk of a high-intensity wild fire occurring in the near future would be less under the action alternatives than under alternative B. A wildfire entering a treated area may result in a greater reduction in ground cover than the proposed treatments alone. Following the proposed treatments, forest floor material would decrease in some areas due to mechanical displacement or consumption by fire, and would increase in other areas due to additions of masticated material. Patches of bare areas would be susceptible to local erosion.

Soil Compaction—Alternative B

Direct Effects

Table 68 shows the extent of detrimental compaction assessed in the field. Under this alternative, the extent and degree of compaction are expected to decline slowly over time. This process may take several decades in forested environments (Grigal 2000). Root penetration, extension, and decay, along with the burrowing action of soil dwelling animals, would contribute to an increase in soil porosity and decrease compaction. In addition, incorporation of organic matter into the soil by biological processes, such as invertebrate and vertebrate soil mixing and decomposition, would help reduce soil bulk density and the degree of compaction in affected areas over time.

Indirect Effects

As the degree and extent of soil compaction is reduced slowly over time, soil physical conditions would return to their pre-compacted state. Soil infiltration would be enhanced as porosity is increased. Increased infiltration may reduce surface runoff and subsequent erosion and sedimentation.

Cumulative Effects

In the absence of future timber harvests, road construction, or other compacting activities, soil compaction is expected to decline as described above. In the event of a future wildfire, severe soil heating may cause physical changes in soils, including a reduction in soil porosity.

Soil Compaction—Effects Common to the Action Alternatives

Direct Effects

Timber harvest and biomass removal would require the use of skid trails and landings. A number of skid trails and landings exist within the treatment units, and it is predicted that some of these will be re-used to implement the proposed activities. The use of heavy forestry equipment and frequent stand entries would increase the potential for soil compaction (Powers et al. 1998). Mastication operations are not expected to result in increases in the extent of detrimental compaction. For any mechanical harvest, the extent and degree of compaction would depend on site-specific soil conditions such as texture and stoniness, moisture content at the time of operations, and harvest equipment features. Project design criteria include implementation of BMPs and other soil protection measures, such as wet weather standards, to minimize soil compaction. Erosion control and compaction remediation measures for landings and skid trails are addressed by BMP 1-16 (“log landing erosion prevention and control”) and BMP 1-17 (“erosion control on skid trails”).

Soil porosity and compaction monitoring results reported in the 2007 HFQLG Soil Monitoring report stated that a review of monitoring data indicates that legacy compaction is commonplace. Most of the detrimental compaction observed post-project also existed pre-project (USDA 2010c). Statistical analysis for 40 thinned units and 11 group selection units determined that the mean post-project areal extent of detrimental compaction as not statistically different from the pre-project mean. Confidence intervals indicated broad ranges that suggested both a trend toward increasing the extent of detrimental compaction and a trend toward decreasing extent.

Indirect Effects

A growing body of recent research suggests that compaction is not always detrimental to forest productivity. For example, after 10 years of growth, the North American Long-Term Soil Productivity (LTSP) experiment has found that soil productivity was both positively and negatively affected by compaction treatments (Powers et al. 2005). In this comparison of 26 study sites, the effects of compaction depended on soil texture. In general, sandy soils showed improved productivity in compacted soil, clayey soils had reduced growth, and loams showed no apparent trend. Soils in the Keddie Ridge treatment units are largely dominated by loamy soil textures, often with a high component of coarse fragments. The risk of compaction in these texture classes is generally moderate. However, compaction of soils in these texture classes may not necessarily reduce site productivity. The wet weather operation soil protection measure would reduce compaction effects. It is important to note that the LTSP study utilizes extreme levels of soil compaction; a mechanical roller, typically used for compaction of highway subgrades, was used to compact the test plots at optimum moisture for compaction. Tree growth is influenced by many factors, including the climate regime, soil aeration, moisture and nutrient availability, soil strength, root-soil interactions, soil mass flow and diffusion properties, and numerous other factors.

Compaction may influence some of these characteristics and thereby influence plant growth and soil productivity.

Cumulative Effects

The extent of detrimental compaction, as defined by the R5 guidance, is difficult to predict due to the environmental and operational variables discussed above. With the incorporation of the design criteria for this project, and the fact that a large number of the units have a moderate compaction potential, it is reasonable to expect that only a portion of the new skid trails would contribute to the cumulative amount of detrimental compaction. Monitoring of detrimental soil compaction has occurred within the HFQLG Pilot Project area. These data suggest that each harvest entry into an area will add a little bit of compaction (USDA 2006e). The cumulative effect of the mechanical operations proposed in the Keddie Ridge Project is likely an increase in the extent of detrimental compaction. This increase, however, may not result in any measurable change to soil productivity for the reasons discussed above. In the LTSP study, an extraordinary effort was used to compact the soil for research purposes. The expected extent of detrimental soil compaction for each of the action alternatives would not be of a size or pattern that would result in significant change in production potential for the activity area.

Down Woody Material—Alternative B

Direct Effects

The applicable standards for large down wood are in the LRMP as amended, which states that down woody material retention levels should be determined on an individual project basis. For the Keddie Ridge Project, 10 to 15 tons per acre of the largest down logs, where they exist, will be retained. The Region 5 Soil Handbook provides a threshold for large woody material, recommending retention of 5 logs per acre representing the range of decomposition classes. Table 68 shows the level of down woody material measured during field sampling. Many units have well over the recommended threshold level. Under the no action alternative, snags are expected to fall, and down wood loads (in terms of tons per acre) and the number of logs per acre are expected to increase. However, in the event of a future wildfire, some down logs are likely to be consumed, particularly those in later decay stages. While rotten logs can retain moisture late in the summer season, some years are quite dry and rotten logs could easily be consumed by fire.

Indirect Effects

In the absence of fire, the increase in down woody material could alter the microclimate and microhabitat at the forest floor. If down wood does retain moisture late in summer (compared with litter and duff materials), this could result in very small-scale changes in nutrient cycling and microbial activities. For example, rates of net nitrogen mineralization may be increased near the logs due to the increased moisture. However, these changes are unlikely to have significant influences over stand productivity because down wood generally covers only a very small proportion of the forest floor.

Cumulative Effects

Under the no action alternative, down wood would continue to accumulate. Overall, levels of down wood are currently very high in the sampled units. This is due largely to heavy deadfall following a drought period. At a localized scale, the wood load may alter nutrient cycling, but this is likely inconsequential in terms of soil productivity. Large amounts of down wood contribute to a heavy fuel load in many units. If a wildfire were to enter the units, much of the wood may be consumed. Heavy fuels such as logs contribute large amounts of heat to the soil during the glowing combustion phase of a fire. In the event of a fire, this intense heat load could produce localized areas of non-wettable soils and strong alterations of mineral soil properties (Moghaddas and Stephens 2007). This could result in long-term reductions in soil carbon and other stored nutrients that contribute to long-term soil productivity.

Down Woody Material—Effects Common to the Action Alternatives

Direct Effects

Mechanical operations would likely rearrange down woody material on the forest floor. Some new woody debris may be created if hazardous snags are felled and left on site. Mastication would add woody material to the forest floor, but these would occur as shredded materials and not logs, as recommended by the R5 guidance. Prescribed burning would consume some of the heavy wood loadings known to exist in the project area. If prescribed burning occurs in the fall, rotten logs may be more susceptible to consumption by fire compared to spring burning, however this would largely depend on the precipitation patterns preceding the burn period.

Large woody material monitoring results from the 2007 HFQLG Soil Monitoring report stated that large woody material decreased from levels observed during pre-treatment monitoring. Only 62 percent of the thinning units and 18 percent of group selection units met the recommended guideline of 5 large down logs per acre under the post-project condition, whereas 85 percent of the thinning units and 73 percent of the group selection units met the guideline under the pre-project condition. The 2009 HFQLG Soil Monitoring Report states that some of this wood was likely removed to meet fuel reduction objectives. A 2008 letter from the three Supervisors of the HFQLG Forests describes management techniques to bring Forests into compliance with soil standards, including the standard for large down wood (USDA 2008f). These techniques include coordination between sale administration personnel and fuel treatment personnel to reduce the loss of large down wood during harvest and burning operations and would be applied on the Keddie Ridge Project to assure that the project standard for large down wood would be achieved under action alternatives.

Indirect Effects

Reductions in large woody material would cause minor, localized changes to soil microhabitat. As described for alternative B, rotten logs can retain moisture longer during the summer season compared with litter and duff materials. A loss of logs and subsequent change in moisture conditions could result in changes in nutrient cycling and microbial activity at the location of the log. This change is expected to be insignificant at the stand scale. Areas of high wood loads in the Keddie Ridge Project are often “jack-strawed,” with woody materials accumulated atop each other. When wood is not in direct contact with the ground, its decomposition rate is greatly reduced. As a result, areas with heaviest wood loads are unlikely to have a large increase in moisture-retention abilities because much of the wood is relatively sound and elevated off the soil surface. Underburning areas of heavy wood loadings could result in localized effects to the underlying soils. The underlying soils are heated during combustion of woody materials. Prescribed burning is designed to occur when soils are moist, which reduces heat transfer and the resulting changes to soil chemical and biological properties.

Cumulative Effects

Reductions in large woody material are expected as a result of the treatments. Currently, many units have wood loadings that are well above the R5 recommended levels 5 logs per acre. The Keddie Ridge landscape likely supports a much higher level of large wood now than during the pre-fire suppression era. In the Keddie Ridge landscape, these woody fuels currently contribute to a heavy fuel loading and increased potential severity during a wildfire. Wildfires tend to occur during late summer when fuels and soils are at their driest. These conditions result in high levels of heating and chemical, physical, and biological alterations of the soil environment, and high losses of large wood. The proposed treatments are designed to reduce fire behavior in the event of a wildfire. By reducing the heavy wood fuel load during prescribed conditions, the resulting changes to the soil will be greatly reduced. Where it exists, 10-15 tons per acre of the largest woody materials would be retained by the project activities.

Fine Organic Matter—Alternative B

Direct Effects

Under the no action alternative, fine organic matter can be expected to increase as organic materials accumulate on the forest floor. Existing levels of fine organic matter are shown in Table 68 and are expect to steadily accumulate over time.

Indirect Effects

As a result of increased cover of fine organic matter, the risk of soil erosion may decline on forested hill slopes. Fine organic matter functions as effective soil cover, which was discussed above. The continued accumulation of organic matter on the forest floor would contribute to increased ground and surface fuel loads, which may lead to increased fire severity and intensity during a fire event.

Cumulative Effects

If fine organic matter were consumed during a wildfire, the soil would be more susceptible to erosion. During a precipitation event, soil can become saturated and erode downslope due to rill formation and raindrop splash. Immediately following a fire, the affected stand may not meet the R5 guidance that recommends 50 percent cover of fine organic matter. However, within several months, a thin layer of needles dropped from scorched trees would likely increase surface cover of organic matter (Pannkuk and Robichaud 2003).

Fires short circuit the decomposition pathway, rapidly oxidizing organic matter and releasing available nutrients to plants and soil organisms. Terrestrial cycling pathways return some nutrients relatively quickly. Compared to the pre-burn condition, a large reduction in the organic matter covering the soil would reduce the insulating effect this layer has on soil temperature. Under a reduced organic layer, soils would experience greater temperature extremes. In addition, a blackened surface, due to partially combusted organic materials, would absorb more light and become warmer than a soil without a dark surface (Ahlgren and Ahlgren 1960). Soil temperatures may be elevated for months or years depending on the degree of organic matter consumption (Neary et al. 1999). Such changes in the soil temperature regime would affect the rates of biological activity in the soil, resulting in altered nutrient cycling regimes.

Fine Organic Matter—Effects Common to the Action Alternatives

Direct Effects

Pre-existing organic matter would be rearranged due to harvesting and yarding equipment. Accurate prediction of treatment effects on surface fine organic matter is difficult but trends would likely be consistent with those observed for effective soil cover in the 2007 HFQLG Soil Monitoring Report (described above). For example, the 2007 HFQLG Soil Monitoring Report presented a statistically significant difference between the pre- and post-project means for effective soil cover on 39 mechanical thinning units, with the 95 percent confidence level describing a post-project reduction in the areal extent of soil cover ranging from 9 percent to 15 percent. A similar reduction of fine organic matter can be expected for the thinning units under this project, indicating that some of the units may, in the short-term, be below the Handbook’s recommended threshold of 50 percent. After the initial reduction in fine organic matter due to mechanical thinning treatments, fine organic matter would increase over the years due to needle cast and leaves falling from coniferous and deciduous trees that remain. Mastication would contribute to fine organic matter increases because shredded materials are broadcast into the unit away from the masticator. Pile burning and underburning would reduce cover of fine organic matter. Pile burning would remove forest floor materials locally, and underburning is expected to occur under prescribed conditions that would not result in complete combustion of the duff and litter layers.

Indirect Effects

Changes in the cover of fine organic matter will affect the risk of erosion, as discussed for effective soil cover, discussed above. Increases in fine organic materials, where units are not subsequently underburned, would add to the total nutrient pool stored in the forest floor. These nutrients are largely unavailable to plants in their organic forms, and are slowly decayed and recycled by soil organisms. As a result of the decomposition process, nutrients are released in available form for uptake by plants and other organisms. When prescribed burning activities consume fine organic matter, essential nutrients can be transferred downward into the soil (Moghaddas and Stephens 2007) or to the atmosphere through volatilization and ash convection (Khanna and Raison 1986). Terrestrial cycling pathways return some nutrients relatively quickly. Burn prescriptions are designed to prevent total consumption of fine organic materials. For example, district watershed staff observed that during underburn operations on the Green Flat Project, the duff layer was left largely intact despite the prescribed fires. As discussed above, scorched needles contribute new inputs of fine organic matter shortly after prescribed fire operations.

The Long-Term Soil Productivity study described above is investigating how substantial removal of forest organic matter affects site productivity. The national ten year results indicate that bole only and whole tree organic matter removals, similar to the thinning treatments proposed for this project, have had no detectable effects on soil nutrition or biomass productivity. Significant reductions in soil carbon and nutrient availability were observed only for the extreme case of whole tree removal plus complete removal of all surface organic matter on the forest floor. However, the data trend indicated no general decline in biomass productivity across any of the organic matter removal levels. Given the modest and short-term reductions of fine organic matter that are expected due to the proposed treatments, those reductions would not significantly change the soil production potential within the proposed units.

Cumulative Effects

The mechanical harvest treatments proposed in the action alternatives and the prescribed burning activities would cause reductions in fine organic matter. Overall, the cumulative effects of the proposed activities, when considered with the past, present, and future activities, are expected to result in fine organic matter conditions that meet the R5 recommended levels. Increases in fine woody materials on the forest floor due to mastication may cause short-term changes in decomposition and carbon and nutrient dynamics in affected areas. Microorganisms that decompose wood would immobilize nitrogen and other nutrients while decaying the woody material. As the wood decomposes, those nutrients would be released and made available to plants and other organisms (Swift et al. 1979). Microclimate changes at the forest floor due to reduced canopy cover could alter rates of decomposition and nutrient turnover in the surface fine organic matter of harvested stands (Erickson et al. 1985). Any reductions below the 50 percent recommended levels are only expected in the underburn units, however these would also be expected to quickly increase due to litter inputs from scorched vegetation. The extent of fine organic matter reductions due to proposed activities for each of the action alternatives would not be of a size or pattern that would result in significant change in production potential for the activity area.

Hydrology Analysis

Effects Common to Alternatives A, C, D, and E

Direct and Indirect Effects

Harvest activities with heavy equipment can result in the creation of new skid trails and an increase in the extent of compacted soil. Prescribed burning would reduce the amount of ground cover. The additional effects of entering RHCAs with vegetative treatments would include increasing the size of residual trees within RHCAs. In order to help maintain favorable microclimates in RHCAs, hardwoods would be retained in all units. This is especially important in the known trout fishery streams, including Wolf Creek, Lights Creek, and Indian Creek. In-stream flows would be assessed during equipment operations, with respect to drafting requirements. Harvest activities may locally alter soil moisture regimes and subsequent water yield due to altered interception and evapo-transpiration due to the decrease in canopy cover.

Prescriptions for the Keddie Ridge Project include product removal, underburning, and mastication. The harvest operations (product removal) would cause associated disturbance from skid trails, site preparation, and transportation needs, such as temporary roads. Underburning would result in reduced ground cover and increased exposure of bare soil. Following implementation, the remaining canopy and vegetative recovery would contribute to rebuilding forest floor materials. Erosion and sedimentation that may result from the activities could decrease the quality of coldwater fish habitat by infilling pools and embedding spawning gravels. Due to ground disturbance, harvested areas would be more susceptible to erosion and sediment transport to the channel network. However, implementation of best management practices would help mitigate and prevent increased compaction and recent results of BMP monitoring on the Plumas Nation Forest demonstrate that BMPs are effective at preventing erosion and sedimentation (USDA 2009a). Over the past three monitoring seasons (2007-2009), 186 evaluations of BMPs were conducted for practices associated with timber and fuel management activities. BMPs were rated as effective for over 88 percent of those evaluations (USDA 2009a). The BMP deficiencies observed were predominantly due to legacy effects associated with the original design or location of system haul roads.

Legacy road designs often incorporated in-sloped road surfaces that drained to an inside ditch rather than current design practices that utilize, as often as practicable, out-sloped road surfaces that disperse runoff. In-sloped designs concentrate road runoff in the inside ditch and the legacy design roads—most constructed prior to existence of the Federal Clean Water Act—did not include sufficient frequency of drainage structures to disperse road runoff and prevent the ditches from delivering sediment to streams at road crossings. Legacy designs that located roads at mid-slope locations typically have higher road-intercepted runoff volumes than roads near ridgetops and mid-slope locations also result in frequent stream crossings. When the 2007-2009 timber BMP evaluations are considered without the road evaluations, the resulting set of 67 evaluations had a 95 percent effectiveness rate. Road reconstruction activities are proposed for all action alternatives to reduce sedimentation impacts associated with legacy road designs.

The road treatments consist of measures to improve road drainage, reduce erosion caused by road drainage, and reduce sedimentation from roads into the stream network. Most roads in the affected subwatersheds have an in-sloped roadbed that is drained by an inside ditch. Culverts occur at varying intervals to drain the ditch, resulting in concentrated flows from the culvert outlets. The road treatments largely include obliterating the ditch, where possible, and reshaping the roadbed so that it is out-sloped. This would allow for dispersed road drainage that is not concentrated by culverts. Where ditch obliteration is not possible, armored rolling dips will be constructed to somewhat disconnect the inside ditch from stream crossings. Culvert outlets will be armored as needed to reduce erosion downstream of the culvert. This armoring will provide roughness to reduce the energy of the water flowing from the culvert and will encourage sediment deposition near the culvert, rather than traveling on toward a stream channel.

Proposed mechanical noxious weed treatments include hand pulling, weed-whacking, and pulling individual plants with a weed wrench. Ground disturbance due to these activities would be negligible—weed pulling may loosen the soil at a local scale. Treatment of noxious weeds with herbicide would occur in all action alternatives and is discussed in a separate section below.

Short-term sediment delivery to streams could potentially occur after prescribed burning due to loss of ground cover. Based on 28 prescribed fire BMP evaluations completed on the Plumas National Forest over the last three years, no short-term sediment delivery to streams after prescribed burning was documented (USDA 2009a). Scorched conifers often drop needles following low or moderate-severity fires and this needle cast would provide ground cover that may help reduce rill and inter-rill erosion and sediment delivery (Pannkuk and Robichaud 2003). Treatments in RHCAs may increase the vigor of riparian vegetation due to increased water yield and reduced competition by conifers. By removing conifers from RHCAs, short-term decreases in channel shading may occur that could affect stream temperatures until riparian vegetation fills these voids. The main objective is to reduce the potential for catastrophic wildfire, and thus, retain the RHCA's desired riparian and aquatic habitats, effective stream channel function, and the ability to route flood discharges.

Road construction would create new sources of sediment and disrupt the hydrologic continuity on affected hillslopes. However, state-of-the-art road design BMPs would be followed for new road construction, including out-sloping of the road template and installation of frequent road drainage structures to minimize delivery of sediment to adjacent streams. Road reconstruction would consist of brushing, blading the road surface, improving drainage, and replacing or upgrading culverts where needed. Road drainage improvements would be designed to disperse runoff and eliminate the occurrence of road drainage being hydrologically connected to adjacent stream channels. Short-term increases in sediment during road reconstructions would be minimized by BMPs and would be offset by long-term improvements to water quality as a result of amelioration of hydrologically connected road segments. Road decommissioning may entail culvert removal, subsoiling of the roadbed, recontouring the hillslope, and/or seeding the affected area. Road decommissioning would promote vegetative recovery, which can decrease compaction, increase infiltration into the roadbed, and increase soil stability and limit concentrated flow as well as surface erosion. Over time, decommissioned roads would produce less sediment and surface runoff to adjacent watercourses. Kolka and Smidt (2004) reported that recontouring hillslopes significantly reduced soil compaction, surface runoff, and sediment production compared to subsoiling or cover cropping.

Cumulative Effects

ERA model values and a discussion of the ERA results relative to TOC for each of the action alternatives is presented below in the section titled "Differences in Effects Analysis Across Action Alternatives." Higher ERA values are generally associated with higher peak flows that are more erosive and can lead to increased channel scour and higher sediment loads off-site. Stream channels in poor condition tend to be more sensitive to increases in peak flows because the channels frequently lack an effective root mass to bind streambanks and large organic debris to retain bedload materials. These channels are frequently downcut (have eroded down into the bottom of their channels), and all flow is confined to the channel rather than to a broader floodplain. Given these conditions, sediment is more readily eroded from these channels with subsequent deposition of sediment downstream. Increases in ERA may lead to detrimental effects, including erosion from treated hillsides and chronic sedimentation. Primary factors leading to this would include a reduction of canopy cover, ground disturbance (particularly due to road effects), and loss of ground cover. Road construction would temporarily increase ERA values due to the addition of roaded acres on the landscape, but all new roads constructed for the Keddie Ridge Project would be decommissioned after implementation. Road decommissioning would reduce ERA contributions by roads, and result in long-term beneficial effects on water quality.

The effects of entering RHCAs with vegetative treatments would be similar to those described directly above. Despite the risk of erosion, the greater long-term benefit of treating the RHCAs would be the potential protection from catastrophic wildfire. Other effects would include increasing the size of residual trees within RHCAs, preventing potential catastrophic wildfire, reducing future losses of large diameter trees and large woody debris (LWD) to fire, and increasing future LWD recruitment of intermediate to large logs. In forested stream systems, debris would help maintain channel stability, decrease flow velocity, trap sediment, and protect banks from erosion (Berg et al. 1998). Within the immediate riparian areas, the physical effects derived from in-channel LWD would be sustained because no natural in-channel debris would be removed. Future recruitment of LWD, which is structurally important for channel morphology, channel function, and bank stability, would be encouraged through snag retention requirements and release of existing live conifers. Canada thistle has the potential to replace many grasses and forbs in the riparian zone, thereby reducing species diversity, but treatment of Canada thistle would help control this invasive noxious weed and protect riparian species diversity. Herbicide effects are discussed below.

Alternative B – No Action Alternative

Direct and Indirect Effects (Alternative B)

Under the no action alternative, all subwatersheds would continue to recover, and ERA values would slowly decline to a baseline level over time. In alternative B, surface, ladder, and crown fuels would not be treated on upslope areas or in RHCAs. Noxious weeds would not be treated. Road drainage improvements and decommissioning activities would not occur, so watershed benefits and reductions in ERA values due to road decommissioning would not be realized. Fuel treatment activities would not occur. A future severe wildfire could greatly increase ERA values within and across subwatersheds.

In the short-term, water quality and downstream beneficial uses would remain unchanged. As watersheds recover from past management activities, there may be small improvements in water quality. However, in the absence of road improvements, decommissioning, or obliteration, the transportation system would continue to be a large contributor of sediment to the stream network. The high density of roads and road/stream crossings would continue to affect the hydrologic regime in these subwatersheds.

Cumulative Effects (Alternative B)

None of the subwatersheds that are contained by the greater watershed assessment area exceed the threshold of concern (TOC). Private harvests are expected to continue within the overall watershed assessment area, though it is difficult to predict the location, type of harvest treatments, or number of acres that would be affected. In alternative B, surface, ladder, and crown fuels would not be treated on upslope areas or in RHCAs. Historically, fire has been an integral disturbance agent in riparian systems (Dwire and Kauffman 2003, Everett et al. 1995, Skinner 2003). However, fire suppression has reduced the influence of fire, resulting in fuel accumulation and increased likelihood of large, severe wildfires (Taylor and Skinner 1998). During wildfires, drainages can behave like chimneys, rapidly directing fire upslope through the drainage area. Under alternative B, watersheds would remain vulnerable to the effects of a future severe wildfire. In the event of a future severe wildfire, affected areas may be highly susceptible to erosion, and generate large pulses of sediment to stream channels (Elliot and Robichaud 2001). Sediment may be stored in channels for many years until peak flows mobilize the materials and move them downstream. Large runoff events often follow severe wildfires, resulting in increased peak flows.

Noxious weeds would not be treated in alternative B. As a result, these weeds may spread over time. As above, many occurrences of the noxious weed Canada thistle are located within RHCAs, and pose a potential threat to biological plant diversity in riparian communities. The spread of Canada thistle could decrease the diversity and productivity of native and desired nonnative riparian plant communities.

Direct, Indirect, and Cumulative Effects of Herbicide Application (Alternatives A and D)

Aminopyralid (i.e. Milestone® or equivalent formulation) herbicide treatments would be performed by manual ground application using backpack sprayers at an application rate of 0.05 to 0.11 pounds acid equivalent per acre (lbs a.e./ac). The formulation would also include a surfactant (Competitor® (Wilbur-Ellis Company) which is a non-ionic modified vegetable oil), and a marker dye (Hi-Light™ Blue (Becker-Underwood, Inc.) which is a water-soluble colorant). Aminopyralid would be used to treat dry and upland sites greater than 15 feet from the water's edge. The aquatic formulation of glyphosate (i.e. Accord® or equivalent formulation) is proposed for lowland treatments (between 0-15 feet from the water's edge) and would be applied selectively by hand using a wick applicator at an application rate of 1-3 lbs a.e./acre. The Keddie Ridge Project also proposes to apply a registered borax fungicide (i.e. Sporax or Cellu-treat) to pine stumps greater than 14 inches in diameter in units 45, 46, 49, and 50. The average application rate for borax in thinning areas would be less than 1 pound per acre (approximately 0.5 pounds per acre) with a range of 0.1 lbs/acre to 1.1 lbs/acre. Group selection units within units 45, 46, 49, and 50 could have as much as 2.7 pounds/acre applied.

There is a considerable body of information describing the potential effects on soil and water resources associated with using each of the proposed herbicides. Much of this information is contained in the risk assessments completed by Syracuse Environmental Research Associates, Inc. (SERA 2007, 2003, 2006), under contract to the Forest Service, and in the HFQLG Act Final Supplemental EIS (USDA 2003a). These documents are incorporated by reference into this effects analysis for the Keddie Ridge Project.

The HGQLG Final Supplemental EIS analyzed the likelihood of detection of glyphosate in surface waters following backpack spray application methods and with full implementation of all water quality best management practices. The HFQLG Final Supplemental EIS concluded that it was unlikely that glyphosate would be detected in forest streams in the pilot project area when streamside buffers and ground applications are used. This conclusion was partially based on the white paper, "A Review and Assessment of the Results of Water Monitoring for Herbicide Residues For The Years 1991 to 1999" (Bakke 2001), which compiled and summarized the results from 15 separate water monitoring reports written by hydrologists and geologists on the Angeles, Eldorado, Lassen, Sierra, and Stanislaus National Forests. These reports documented the results of over 800 surface- and ground-water samples taken for reforestation and noxious weed eradication projects that used three herbicides (glyphosate, hexazinone, and triclopyr).

According to "A Review and Assessment of the Results of Water Monitoring for Herbicide Residues for the Years 1991 to 1999" (Bakke 2001), detections of glyphosate have been associated with its use in riparian areas or applications that did not follow established best management practices. The only sited occurrence of a detection occurred in only 1 of 12 samples. The detection was low (15 parts per billion), and the application was by spray in the actual stream channel at greater than 1.5 lbs/acre. In the Proposed action, glyphosate would only be applied by wick application which would effectively eliminate the chance of drift because herbicide is not emitted by spray, and the buffer would be 15 feet from the water's edge. The incorporation of these design elements would greatly reduce the risk of indirect effects due to drift.

The proposed use of herbicides includes the additional use of a surfactant (Competitor®) and a marker dye (Hi-Light™ Blue). Surfactants are used to facilitate or enhance the absorbing, emulsifying, dispersing, spreading, sticking, wetting, or penetrating properties of herbicides. Competitor® is a non-ionic modified vegetable oil. The assessment of hazards related to surfactants is limited by the proprietary nature of the formulations. Surfactants, by their very nature, are intended to increase the effect of a pesticide by increasing the amount of pesticide that is in contact with the target. This is not synergistic, but more accurately a reflection of increased dose of the herbicide active ingredient into the plant. The "Analysis of Issues Surrounding the Use of Spray Adjuvants with Herbicides" (Bakke 2003) sites technical references which indicate a lack of synergistic effects between surfactants and pesticides which suggest that surfactants don't increase the toxic effects of herbicides. This paper also listed the results of standard acute aquatic species toxicity testing which indicated that any potential effects to aquatic species would be unlikely under normal application rates. Studies have shown that mobility of materials throughout the soil profile is a function of the concentration of the surfactants in the soil solution. For this to occur, concentrations of surfactant must be high, in the range of 1,000 ppm or more(Bakke 2003). This level is unlikely to be reached under normal application rates as proposed by this project, which would likely have concentrations considerably, less than 12 ppm. "Although the potential exists for surfactants to affect the environmental fate of herbicides in the soil, any potential effects would be unlikely under normal conditions because of the relatively low concentration of surfactants in the soil/water matrix. Localized effects could be seen if a spill occurred on the soil, so that concentration of surfactant approached or exceeded about 1,000 ppm" (Bakke 2003).

The colorant Hi-Light™ Blue will be added to the herbicide mixtures prior to the application so that the actual treated area can be readily determined. This helps to prevent skips and overlaps. Hi-Light™ Blue is a water-soluble dye that contains no listed hazardous substances. It is considered to be virtually non-toxic to humans. Its effect on non-target terrestrial and aquatic species is unknown, however its use has not resulted in any known problems. The dye used in Hi-Light™ Blue is commonly used in toilet bowl cleaners and as a colorant for lake and ponds (SERA 1997).

Unlike the other two pesticides proposed, the agent of toxicologic concern in borax (i.e. boron), occurs naturally and exposures to this element are unavoidable. The use of borax is not expected to substantially contribute to concentration of boron in water or soil beyond those that are associated with the normal occurrence of boron in the environment (SERA 2006).

Direct Effects

No direct effects on soil productivity are predicted from the proposed herbicide treatment in alternatives A and D. The potential for adverse effects of herbicide residues in soil and water would be minimized or eliminated by incorporating the proposed design criteria and applying BMPs for herbicide application. Design criteria include carefully planned herbicide use according to the label and other relevant requirements, spill contingency plans, proper disposal of containers and cleaning equipment, adequate buffer strips, spray drift control, and restricted use of herbicides near water bodies with sensitive amphibian species.

Drift calculations from the SERA risk assessments (SERA 2003, 2007) analyzed the potential for herbicide drift during applications of glyphosate and aminopyralid. Backpack sprayers were analyzed under two wind speed conditions: (1) 0 to 5 miles per hour (mph) winds in which droplets could drift as far as 23 feet and (2) 15 mph winds with the potential to drift up to 68 feet. Based on these calculations and a 10 mph maximum wind speed for application using a backpack sprayer, the proposed stream buffers would reduce the potential for the herbicide to reach water due to drift. Refer to appendix B of the final EIS for a list of the proposed design criteria for noxious weed treatments.

Mobility and Persistence of Glyphosate

Glyphosate has limited mobility because it tends to adsorb strongly to soil particles, especially to clay and to iron and aluminum ions. While it has high water solubility, it does not tend to leach through the soil profile in most soils. Although glyphosate has a relatively short half-life in soil (25–130 days) (USDA 2003a), adsorption to soil can create an herbicide sink, which may take longer to dissipate. In soils with high sand content (about 80 percent), leaching and longer persistence have been observed (Smith 1996, Eberbach and Douglas 1983). Generally, glyphosate is degraded in soils within three months (USDA 1988). A study in the Journal of Agricultural and Food Chemistry indicated that glyphosate desorbed (the compound detaches from the soil particle) at a higher rate than had been indicated by previous research(Piccolo 1994). The results, however, were obtained by laboratory experiments and were not taken under natural conditions. The compound only detached after several hours of severe mechanical shaking. These conditions do not occur in the natural system.

Mobility and Persistence of Aminopyralid

According to the aminopyralid report completed by SERA in 2007, aminopyralid is quite soluble, and its persistence in soil can vary depending on soil type and other environmental conditions—its half-life can range from 14 to 343 days. Although aminopyralid does not bind readily in soil, it dissipates rapidly in some common soil conditions. No known metabolites of aminopyralid have been identified.

The SERA risk assessment (2007) states that aminopyralid or any other herbicide may be transported to off-site soil by runoff or percolation. Runoff and percolation are both considered in estimating contamination of ambient water. For assessing off-site soil contamination, however, only runoff is considered. This approach is reasonable because off-site runoff will contaminate the off-site soil surface. Percolation, on the other hand, represents the amount of the herbicide that is transported below the root zone and may thus impact water quality.

The probability is very low that a detectable level of either of the two proposed herbicides would reach surface water (flowing streams, springs, seeps, and riparian areas). The probability of the Keddie Ridge Project violating a water quality standard would be very small—this is based on the glyphosate and aminopyralid risk assessments (SERA 2003, 2007) and on the results of over 12 years of monitoring glyphosate in Region 5. At the levels proposed for application, neither aminopyralid nor glyphosate is expected to have direct detrimental effects on water quality.

Mobility and Persistence of Borax

The borax risk assessment states “in water, boron compounds transform rapidly into borates, no further transformation is possible, with borate speciation dependent upon pH. Those compounds may be transported by percolation, sediment, or runoff from soil to ambient water. Borate compounds are adsorbed to soils to varying degrees, depending on several factors, including soil type and water pH” (SERA 2006). A study by the Southeastern Forest Experiment Station in 1971 showed that borax “persisted uniformly at a toxic concentration 5.1 cm below the stump surface for at least 8 weeks. Twenty six months after treatment, borax had leached to subtoxic levels throughout the upper 0.3 cm of stumps, but toxic amounts were measured at a depth of 1.2 cm” (Koenigs 1971).

Soil Microorganisms

According to the SERA (2003) risk assessment, glyphosate is readily metabolized by soil bacteria with aminomethyl phosphonic acid as a major metabolite. In addition, many species of soil microorganisms can use glyphosate as sole carbon. There is very little information suggesting that glyphosate is harmful to soil microorganisms under field conditions, and a substantial body of information indicates that glyphosate would likely enhance or have no effect on soil microorganisms.

In application rates of 1.2 lbs a.e./acre (0.54 kilograms per hectare), a transient decrease in populations of soil fungi and bacteria was noted after 2 months but no effect was apparent after 6 months. Similarly, at an application rate of 7.12 lbs a.e./acre (3.23 kilograms per hectare), no effect was seen on soil fungi and bacteria after 10 to 14 months. A transient decrease in soil microbial activity was also noted after the application, but no lasting effects on soil have been reported (SERA 2003).

Several field studies involving microbial activity in soil after glyphosate exposures note an increase rather than decrease in soil microorganisms or microbial activity. Application of glyphosate may cause transient increases in soil fungi that may be detrimental to some plants, and some studies have shown that inoculation of soil with various pathogenic soil fungi may result in an apparent enhancement of glyphosate toxicity (SERA 2003).

Aminopyralid toxicity data on soil organisms are limited, but the projected maximum concentrations under normal application rates would be far below potentially toxic levels. A study by (McMurray 2002) showed modest increases in nitrate and total mineral nitrogen concentrations in soil directly following application but no statistically significant effects were noted thereafter. The information on soil organisms is limited and consists only of a no-observed-effect concentration (NOEC) value for earthworms reported as 5,000 ppm (mg a.e./kg soil). The proposed maximum application rate of .11 lbs a.e./acre corresponds to a concentration of about 0.05 ppm and “indicates inconsequential risks to earthworms” (SERA 2007). Consequently, this information does not provide any basis for asserting that adverse effects on soil organisms are plausible.

Borates are effective fungicides and some nontarget soil microorganisms could be affected by exposure to boron in soil. “However, information to adequately assess risk in this class of organisms is not available” (SERA 2006). Due to the application method and rates, widespread exposure to soil microorganisms are not likely.

Indirect Effects

Based on a review of the literature and monitoring reports from other Region 5 herbicide projects, the proposed spray treatments are not expected to significantly increase the potential for erosion. Reducing the amount of ground cover protecting the soil, and thus increasing erosion rates, is a potential indirect effect. However, it is expected that none of the action alternatives would significantly reduce existing ground cover in treated areas. Litter and duff inputs may be reduced slightly, due to the reduction in shrub canopy, but existing litter and duff would continue to provide an adequate amount of ground cover. Vegetation killed by herbicides would continue to provide a canopy cover until the leaves fall, which would then add to the existing ground cover.

Cumulative Effects

Glyphosate and aminopyralid are not expected to accumulate in the soils within the project area. According to the HFQLG Final Supplemental EIS, “Surface water concentrations of glyphosate and aminopyralid are anticipated to be undetectable, assuming backpack application using BMPs, and no cumulative effects are anticipated from application of these herbicides, because their delectability is anticipated to be zero” (USDA 2003a). A cumulative watershed effects analysis explores the potential for possible cumulative indirect effects on hydrologic function as a result of removing vegetative cover, ground disturbance, and soil compaction. Since the proposed herbicide treatments would not result in additional bare or compacted soil, the proposed herbicide treatments would not result in new ERAs that would change the results of the cumulative watershed effect ERA analysis. In fact, the HFQLG Final Supplemental EIS determined through modeling that the watershed effects of herbicide maintenance treatment would be small, relative to other disturbances within watersheds of the HFQLF pilot project area, and would not significantly increase cumulative watershed effects (USDA 2003a).

Previous discussion reveals that there is little chance that either glyphosate or aminopyralid is expected to reach streams because of their limited transport mobility; relatively short half-lives; buffers along streams; application criteria, which takes into account the time of year, wind velocity, and period to the next rainfall; and other BMPs for herbicide application. In conclusion, no significant adverse cumulative watershed effects associated with the herbicide application alternatives are expected.

Effects Analysis – Action Alternatives

Cumulative Effects

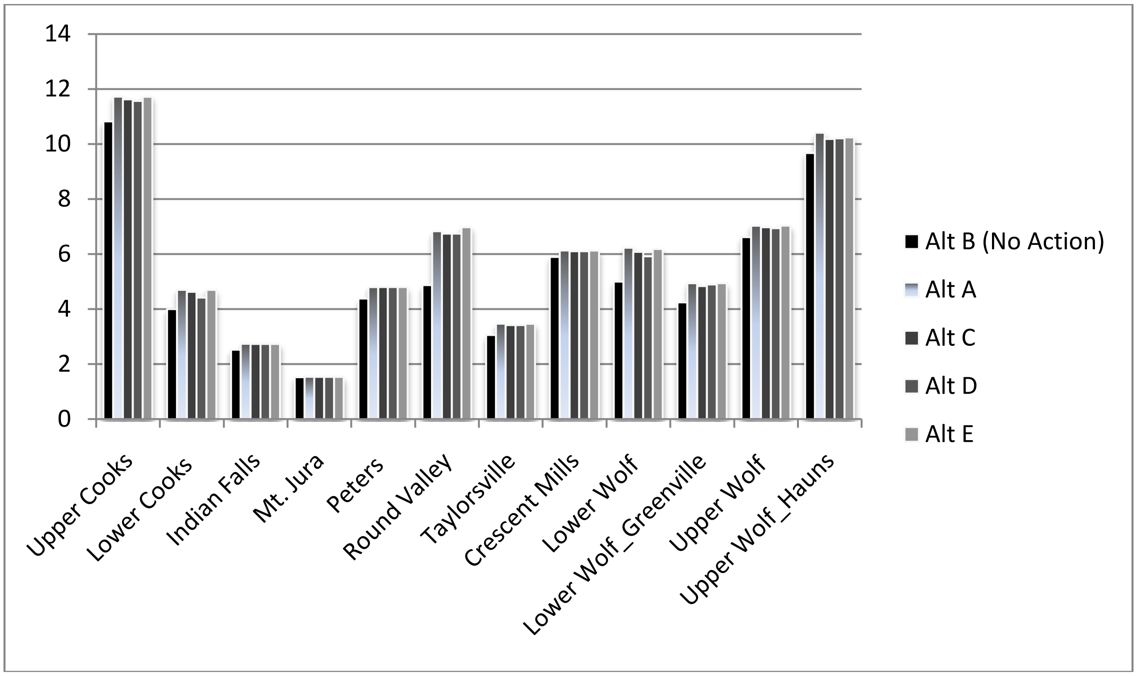

Figure 16. ERA Comparison by Alternative

Alternative A—Cumulative Watershed Effects, ERA Analysis

Direct, indirect, and cumulative effects of activities proposed in alternative A are discussed above in the section subtitled, “Effects Common to Alternatives A, C, D, and E”. Alternative A, the Proposed action, would construct 5,175 acres of Defensible Fuel Profile Zones (DFPZs); implement 494 acres of area thinning (AT) outside of DFPZs; implement 284 acres of group selection (GS) within DFPZ and AT units. This alternative would also hand thin, pile, and burn within 9 acres of clustered lady’s slipper habitat and 76 acres of Constance’s rock cress habitat. Alternative A would additionally treat 107 acres of noxious weed infestations using a combination of herbicide applications of aminopyralid or glyphosate, hand pulling, late spring underburning and direct flaming with a backpack propane torch, and revegetation in select areas using native seed.

Under alternative A, the project-induced increase in ERA values were predicted to range from .01 to 16.3 percent of the TOC, depending on the subwatershed. This would result in cumulative ERA values ranging from 12.8 to 97.6 percent of the TOC. Riparian area ERA value increases induced by alternative A would range from 0 to 1.5 percent depending on the subwatershed. Treatment activities would not cause any subwatersheds to exceed the TOC (Figure 16) and only one subwatershed (Upper Cooks) would approach the TOC. The Moonlight Fire and subsequent private salvage harvest activities raised the ERA value in the Upper Cooks Creek subwatershed to 90.2 percent of TOC, and the Keddie Ridge

Project would raise it another 8 percent. Consequently, it is at a high risk for detrimental watershed effects.

A closer look in the field at riparian areas for the Upper Cooks watershed indicate that these areas are stable and well-vegetated and would provide effective buffers for any potential project-generated sediment delivery. Proposed road reconstruction within this watershed would eliminate occurrences where road drainage enters stream courses. The observed existing condition of stream channels and adjacent riparian buffers, along with implementation of project BMPs and design features, assure that significant impacts to water quality and beneficial uses would not occur in this subwatershed. An adverse cumulative watershed effect due to implementation of alternative A is not expected for any of the project subwatersheds.

The Round Valley Reservoir subwatershed, the municipal water supply for Greeneville, is projected to experience the greatest increase in ERA—16.3 percent, bringing the ERA value up to 6.83 which equates to merely 56.9 percent of the 12.0 ERA threshold. This subwatershed is also projected to experience the highest riparian area ERA increase, 1.5 percent above existing condition and therefore pose a greater risk for cumulative effects. However, for purposes of the CWE analysis, it is important to mention that the internal equipment exclusion zones of RHCAs and were not removed from the total treatment acreage proposed in action alternatives. Therefore, ERA values for sensitive areas are conservative estimates within the analysis subwatersheds. Field surveys of the watersheds and associated stream systems that are above or near the TOC were conducted to verify stream channel and hillslope conditions and properly select project design elements that would reduce the risk of detrimental effects to the soil and water resources. RHCA and SMZ equipment exclusion zones would be delineated out and avoided in accordance to the equipment restriction zones defined in Table 70. Refer to appendix H of the final EIS for a complete list of standard management requirements associated with RHCAs.

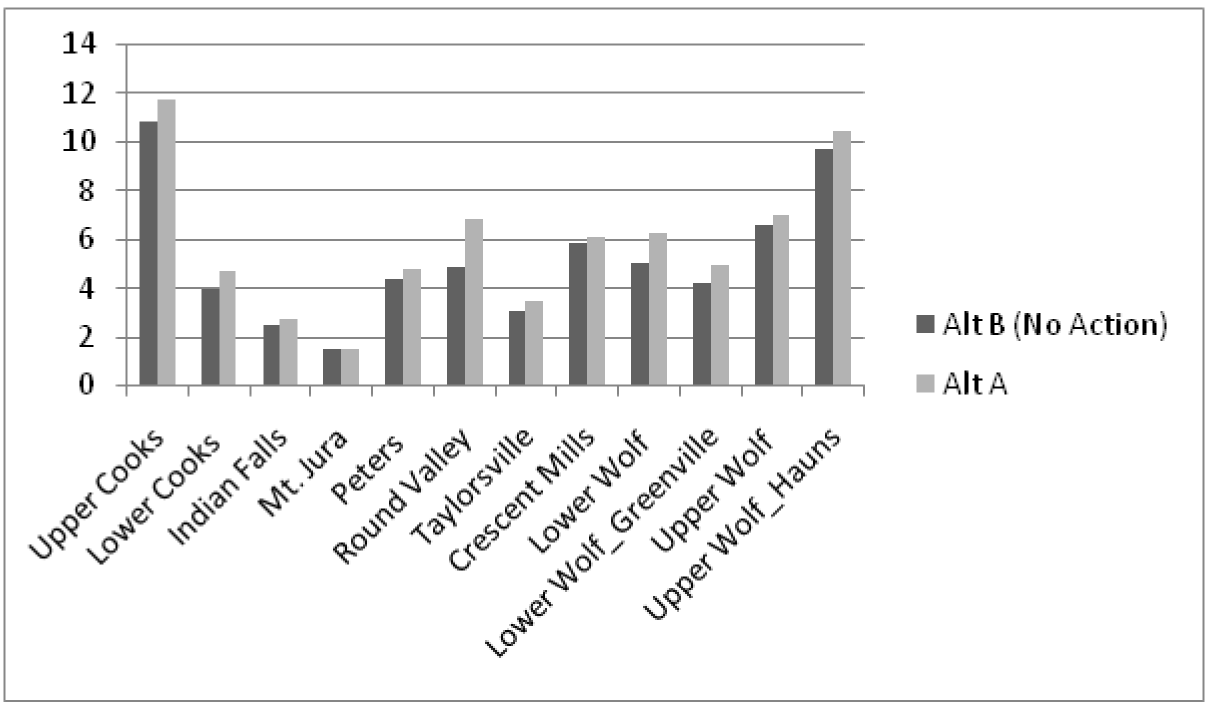

Figure 17. ERA of Alternative A Compared to the No Action Alternative

Alternative B—Cumulative Watershed Effects, ERA Analysis

Consequences of the no action alternative are thoroughly covered in the “Direct, Indirect, and Cumulative Effects of DFPZ and WUI Fuels Reduction Treatments (alternative B)” section above.

Alternative C—Cumulative Watershed Effects, ERA Analysis

Direct, indirect, and cumulative effects of activities proposed in alternative C are discussed above in the section subtitled, “Effects Common to Alternatives A, C, D, and E”. Alternative C, the non commercial funding alternative, is required in all projects with purpose and needs that include fuels reduction and excludes any activities other than fuels reduction to meet the project purpose and needs. Alternative C proposes 5,431 acres of DFPZ construction and 522 acres of AT outside of DFPZs, while retaining all live trees greater than or equal to 12 inches in both DFPZs and AT units.

ERA values for this alternative (Figure 18) are only slightly less than the Proposed action (alternative A) primarily due to the lack of the group selection (GS) prescription. The project-induced increase in ERA values were predicted to range from .01 to 15.6 percent of the TOC depending on the subwatershed. Riparian area ERA value increases induced by alternative C would range from 0 to 1.5 percent of the land area, also depending on the subwatershed (refer to “Alternative A—Cumulative Watershed Effects, ERA Analysis” for an explanation of the greater risk of cumulative effects).

Subwatershed cumulative ERA values would range from 12.8 to 96.8 percent of the TOC. The Upper Cooks Creek subwatershed is the only one that approaches TOC, and is discussed in the “Alternative A—Cumulative Watershed Effects, ERA Analysis” section above. Alternative C also neglects to treat noxious weeds with herbicides, which could allow for the spread of noxious weeds over time. In particular, the spread of Canada thistle in riparian areas could decrease the diversity and productivity of native and desired nonnative riparian plant communities.

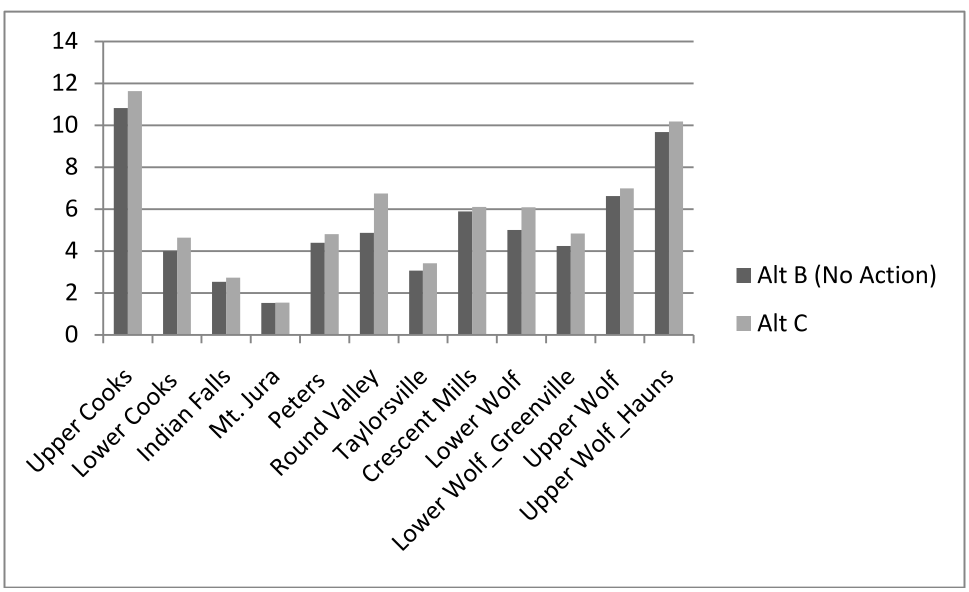

Figure 18. ERA of Alternative C Compared to the No Action Alternative

Alternative D—Cumulative Watershed Effects, ERA Analysis

Alternative D (2001 SNFPA Framework alternative) was requested for analysis during the scoping process. This alternative would construct 4,976 acres of DFPZ; implement 467 acres of AT outside of DFPZ units; hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat, 76 acres of Constance's rock cress habitat, and 12 acres within a bald eagle territory. This alternative would also treat 107 acres of noxious weed infestations using a combination of herbicide applications of aminopyralid or glyphosate, hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. With respect to cumulative watershed effects, alternative D is most similar to alternative C—neither proposes group selection (GS) units and ERA values (Figure 19) consequently are similar and are discussed in the previous alternative. Riparian area ERA value increases induced by alternative D would range from 0 to 1.48 percent of the land area, depending on the subwatershed. These increases are slightly lower than RHCA ERA values for the other action alternatives due to fewer proposed acres of RHCA treatment (refer to "Alternative A—Cumulative Watershed Effects, ERA Analysis" for an explanation of the greater risk of cumulative effects).

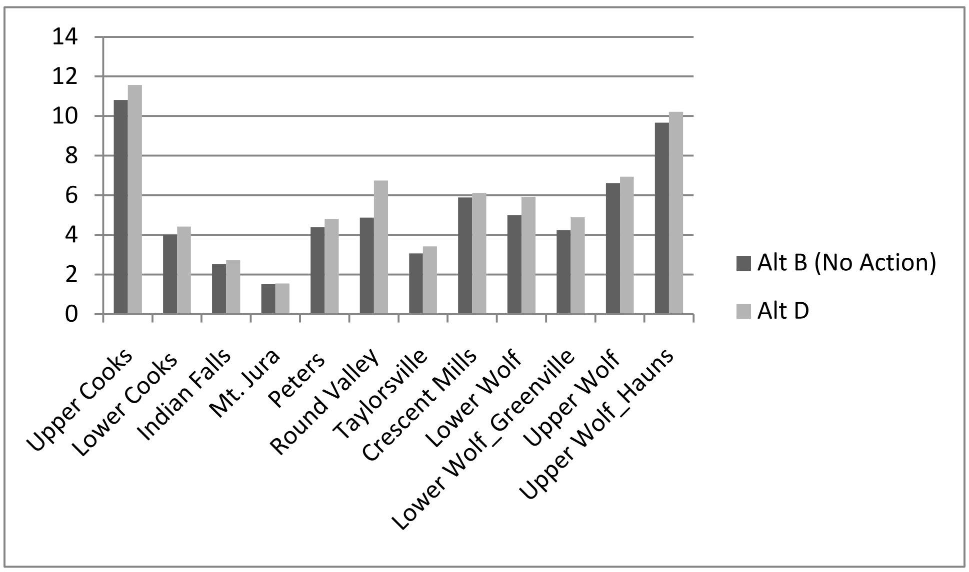

Figure 19. ERA of Alternative D Compared to the No Action Alternative

Alternative E—Cumulative Watershed Effects, ERA Analysis

Alternative E (2004 SNFPA ROD consistent alternative) was also requested for analysis during scoping and analyzes the maximum treatment allowed under the Herger-Feinstein Quincy Library Group Act. It would construct 5,112 acres of DFPZs; implement 513 acres of AT outside of DFPZ units; implement 328 acres of GS within DFPZ and AT units; and hand thin, pile, and burn within 9 acres of clustered lady's slipper habitat and 76 acres of Constance's rock cress habitat. Alternative E would treat 90 acres of noxious weed infestations using a combination of hand pulling, spring underburning, direct flaming with a backpack propane torch, and revegetation in select areas using native seed. No herbicide use is proposed under alternative E. Cumulative watershed effects are expected to mirror those of alternative A, with a higher ERA value (Figure 20) in the Round Valley Reservoir subwatershed due to a larger amount of group selection (GS) acres proposed in alternative E. A discussion of activities affecting Round Valley Reservoir can be found in the “Alternative A—Cumulative Watershed Effects, ERA” analysis above. Riparian area ERA value increases induced by alternative E would range from 0 to 1.5 percent of the land area, also depending on the subwatershed (refer to “Alternative A—Cumulative Watershed Effects, ERA Analysis” for an explanation of the greater risk of cumulative effects).

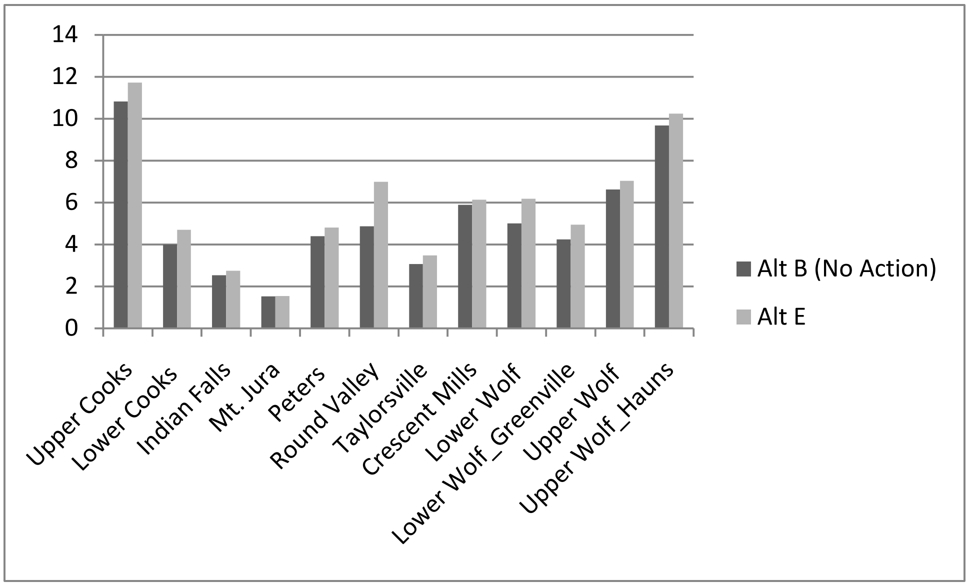

Figure 20. ERA of Alternative E Compared to the No Action Alternative

Botanical Resources

Introduction

The purpose of this section is to present a summary of the effects of the proposed project on botanically sensitive resources within the Botany analysis area. Throughout this section, the term “rare species” is used to refer to federally Endangered, Threatened, and Candidate plant species and Forest Service Region 5 Sensitive species. A complete discussion of effects to these species, as well as to Plumas National Forest special interest species, is provided in the “Keddie Ridge Hazardous Fuels Reduction Project: Biological Evaluation of Potential Effects to Threatened, Endangered, and Sensitive Plant Species” (USDA 2011f), which is located in the project record and incorporated by reference.

Analysis Framework: Statute, Regulatory Environment, Forest Plan, and Other Direction

Regulatory Environment

Federal Laws

Endangered Species Act (16 USC 1531 et seq.): Under this act, federal agencies must ensure that any action authorized, funded, or carried out by the agency is not likely to (a) jeopardize the continued existence of any listed species or (b) result in the destruction or adverse modification of a listed species’ designated critical habitat. Section 7 of the act requires federal agencies to consult the U.S. Fish and

Wildlife Service concerning listed (i.e. threatened or endangered) plant species that fall under their jurisdiction.

Forest Service Manual (FSM) Direction

FSM Section 2670 (USDA 2005a): provides policy for the protection of sensitive species and calls for the development and implementation of management practices to ensure that species do not become threatened or endangered because of Forest Service actions. It requires a review of all activities or programs that are planned, funded, executed, or permitted for possible effects on federally listed or U.S. Forest Service sensitive species (FSM 2672.4, USDA 2005a).

Forest Plan

Plumas NF Land Management Plan (USDA 1988, 1999b, 2004b): provides management direction for all Plumas NF Sensitive plants; that direction is to "maintain viable populations of sensitive plant species" (USDA 1988). The 1988 Forest Plan also provides forest-wide standards and guidelines to:

- protect Sensitive and Special Interest plant species as needed to maintain viability;
- inventory and monitor Sensitive plant populations on an individual project basis; and
- develop species management guidelines to identify population goals and compatible management activities / prescriptions that will maintain viability.

Management direction for sensitive plant species on the Plumas NF is also provided in the Herger-Feinstein Quincy Library Group (HFQLG) Forest Recovery Act Final Environmental Impact Statement (USDA 1999a) and the Sierra Nevada Forest Plan Amendment (SNFPA) Final Supplemental Environmental Impact Statement (USDA 2004a). The standards and guidelines provided in the SNFPA include conducting field surveys, minimizing or eliminating direct and indirect impacts from management activities, and adhering to the Regional Native Plant Policy (USDA 2004a).

Interim Management Prescriptions

Individual species conservation strategies, or species management guidelines, for the Plumas NF have not been completed for most of the Forest's Sensitive species. Until these conservation strategies have been completed, the Plumas NF has developed Interim Management Prescriptions (USDA 2007c) that will be followed to ensure compliance with the Plumas LRMP.

Effects Analysis Methodology

Geographic Area Evaluated

The area analyzed in this document is referred to as the "Botany analysis area"; it encompasses approximately 64,000 acres and consists of all proposed treatment units and the area within one mile of treatment unit boundaries. This area was chosen to capture all rare plants that occur (a) within the proposed treatment units or (b) have suitable habitat within the Keddie Ridge Project area as well as a source population (i.e. potential for seed dispersal) located within close proximity to the proposed activities.

Species Analyzed

Those species present within the Botany analysis area were considered to have the highest potential to be impacted by the proposed project activities. Conversely, species outside of the analysis area were not considered to have a high likelihood of being impacted by the proposed project either directly, indirectly, or cumulatively. Table 71 lists all of the rare species that have been documented within the Botany analysis area. A detailed analysis of effects to these species is provided in the Biological Evaluation (USDA 2011f), which is included in the Keddie Ridge Project record. This document presents the analysis for only those rare species that occur within the proposed treatment units (Table 71).

Table 71. Rare Species Known within Proposed Treatment Units and the Keddie Ridge Botany Analysis Area

Species	Common Name	Listing Status	Known within the Analysis Area	Known within the Treatment Units
Arabis constancei	Constance's rock cress	Sensitive	X	X
Astragalus webberi	Webber's milkvetch	Sensitive	X

Specific Methodology

The analysis of effects on rare plant species was a three-step process (FSM 2672.43; USDA 2005a). In the first step, all listed or proposed rare species that were known or were believed to have potential to occur in the analysis area were identified. This list was developed by reviewing the U.S. Fish and Wildlife List for the Plumas NF (U.S. Fish and Wildlife 2010), USDA Forest Service Region 5 Sensitive Species List (USDA 2006a), Plumas NF rare plant records and vegetation maps, and California Natural Diversity Database records (CNDDB 2010).

The second step was field reconnaissance surveys. To date, field surveys have been conducted on approximately 16,500 acres within the Botany analysis area; this includes all of the proposed vegetation and noxious weed treatment units. For those areas outside of the surveyed areas, but within the Botany analysis area, species occurrence information was compiled using the California Natural Diversity Database (2010), Plumas NF rare plant records, and past survey reports.

Field surveys were designed around the flowering period and ecology of the rare plant species identified in step one. For each rare plant site found, information was collected that described the size of the occurrence and habitat characteristics and identified any existing or potential threats. Location information was collected using a Global Positioning System (GPS).

All of this information was used in step three of the analysis—effects analysis. Data were imported into a Global Information System (GIS) and used to analyze proximity to the proposed treatments and identify direct and indirect effects.

Data Sources

Basic information describing the life history, ecology, pollination biology, and specific habitat requirements is lacking for most of the Sensitive species that occur within the Botany analysis area. The scientific literature and internal government documents (i.e. species-specific Conservation Assessments) were utilized for the analysis whenever available; however more frequently the analysis of effects was based on observations by qualified individuals, field experience, unpublished monitoring results, and studies of comparable species.

Botany Indicator Measures

The indicator measures used in the effects analysis for rare plant species included the number of occurrences and the amount of suitable habitat impacted; these measures were similar across all of the action alternatives.

Types and Duration of Impacts

Direct Effects

Direct effects occur when plants are physically impacted. Examples of proposed treatment activities that have the potential to directly affect rare plants include timber falling; crushing by vehicles or equipment; application of borax or herbicides; temporary road and landing construction; and prescribed fire treatments. These actions can result in death, altered growth, or reduced seed set through physically breaking, crushing, burning, scorching, or uprooting plants.

Indirect Effects

Indirect effects are separated from an action in either time or space. These effects, which can be beneficial or detrimental to rare species, may include changes in vegetation composition, successional patterns, fire regimes, or the distribution and abundance of noxious weeds. Adverse indirect effects are more likely to occur to those species that are intolerant of disturbance and tend to occupy interior forest habitats with high canopy cover. In contrast, for those species that tolerate or are dependent upon some level of disturbance and inhabit gaps and forest openings, treatments may have beneficial indirect effects. For all rare species, negative effects may occur if prescribed burns are too hot; this has the potential to kill the seedbank and sterilize the soil. Burning hand or machine piles can also alter soil biotic and chemical properties for a number of years (Korb et al. 2004), which in turn greatly influences the degree and type of plant colonization into the fire-scarred site. Other indirect effects that are associated with herbicide treatments may include impacts to pollinators or mycorrhizae (fungi) that are associated with rare species.

Cumulative Effects

A cumulative effect can result from the incremental effect of the current action when added to the effects of past, present, and reasonably foreseeable future actions. These effects are considered regardless of what agency or person undertakes the other actions and regardless of land ownership on which the other actions occur. An individual action when considered alone may not have a significant effect, but when its effects are considered in sum with the effects of other past, present, and reasonably foreseeable future actions, the effects may be significant (40 CFR 1508.7 and 1508.8 and FSH 1909.15 section 15.1).

One crucial step in assessing cumulative impacts on a particular resource is to compare the current condition of the resource (i.e. rare plants) and the projected changes as a result of management activities (i.e. timber harvest) to the natural variability in the resources and processes of concern (MacDonald 2000). This assessment is particularly difficult for rare plant species because long-term data are often lacking. In addition, the habitats in which many rare plant species are presently found have a long history of disturbance, making an undisturbed reference difficult to find. For some rare plants, particularly those that do not tolerate disturbance or are found under dense canopy conditions, minimizing on-site change is an effective way of reducing the potential for larger-scale cumulative impact (MacDonald 2000). If the greatest impact on a rare species is both local and immediate, then this is the scale at which the effect is easiest to detect (MacDonald 2000).

Undeniably, past, present, and future activities have and will continue to alter rare plant populations and their habitats to various degrees; however, the approach taken in this analysis is that, if direct and indirect adverse effects on rare plant species in the Keddie Ridge Project are minimal or would not occur, then they would not contribute substantially to cumulative effects on the species. In addition, the effects of future projects would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place

Duration of Effects

It is difficult to state with certainty when the effects of the proposed treatments would no longer be altering the life history dynamics (i.e. germination, seed production, etc.) of the rare species considered in this analysis. One method to estimate duration of effects is to assume that the effects of the action alternatives last as long as they are, singly or in combination with other anticipated effects, distinguishable from the effects of the no action alternative. Using this as an assumption, the duration used to estimate effects in this analysis is the recovery time of the vegetation to near baseline (current) conditions, which is approximately 100 years for group selection treatments and 50 years for fuel treatments.

The additive effects of past actions (such as wildfires, wildfire suppression, timber harvest, mining, nonnative plant introductions, and ranching) have shaped the present landscape and corresponding populations of rare plants; however, data describing the past distribution and abundance of rare plant species is extremely limited, making it impossible to quantify the effects of historic activities on the resources and conditions that are present today. Undoubtedly, some plant species have always been rare due to particular ecological requirements or geographic isolation. It is also likely that past actions have caused some species to become rarer and encouraged others to become more common. Within the Botany analysis area, documentation of rare plant surveys began in the early 1980s; therefore, the baseline used for the effects analysis of past activities is 30 years.

Affected Environment

Rare Plant Species

Constance's rock cress (*Arabis constancei)*

Constance's rock-cress is a strict serpentine endemic (Safford et al. 2005) that is considered to be seriously threatened in California (List 1B.1; CNPS 2010). It is known from 55 occurrences, which are scattered throughout several parallel bands of serpentine in Plumas and Lassen Counties. All but one of these occurrences are located on the Plumas NF; the occurrence outside of the Plumas NF is in the southernmost part of the Lassen NF (CNDDB 2010).

Occurrences are found primarily in undisturbed sites that are situated between 3,200 and 6,600 feet in elevation. They range in size from a few individuals on small serpentine outcrops to hundreds of individuals within larger areas of more productive serpentine soils. Occurrences that have not been impacted by management activities appear relatively stable over time; however analyses of monitoring data collected over a 20 year time period suggest that the number of plants can fluctuate from year to year, possibly in response to variation in precipitation or other climatic variables (USDA 2007b, 2008b).

Six occurrences of Constance’s rock cress, covering approximately 162 acres, have been documented within the Botany analysis area. Two occurrences, covering approximately 72 acres, are within treatment units 64 and 71 (Table 72). Hand thinning treatments, which have been designed to enhance Constance’s rock cress habitat, are proposed within these two occurrences. Constance’s rock cress does not occur within any of the proposed noxious weed treatment units.

Table 72. Comparison of Constance's Rock-Cress Abundance at the Global, State, Forest, and Project Scale

Species	Global Ranking	Number of Occurrences			
		California	Plumas NF	Keddie Analysis Area	Treatment Units
Arabis constancei	G3[1]	55	54	6	2

[1] G3 = vulnerable to extirpation or extinction; 21 to 80 occurrences, OR 3,000 to 10,000 individuals, OR 10,000 to 50,000 acres (NatureServe 2009)

Clustered lady’s-slipper (*Cypripedium fasciculatum)*

This orchid has a wide distribution that extends from British Columbia, south to the Sierra Nevada and Coast Ranges of California, and east to the Rocky Mountains. While the distribution of this species is broad, occurrences are often small and widely scattered. In California, the highest distribution of clustered lady’s-slipper is on the Klamath and Plumas National Forests. There are 148 occurrences on the Plumas NF; these range in size from one to over 3,000 stems. A total of 200 occurrences have also been recorded on the Six Rivers, Shasta-Trinity, Klamath, Mendocino, and Tahoe National Forests (Kaye and Cramer 2005).

In California, clustered lady’s-slipper is most commonly associated with mixed conifer forests in the mid-to-late stages of successional development. On the Plumas NF, plants most frequently occur in microsites with moist soils, steep slopes, sufficient dogwood (*Cornus nuttallii*) cover, and a relatively open overstory canopy (Brown 2008). Clustered lady’s-slipper orchids lack physiological adaptations to regulate and tolerate drought and heat stress; therefore they depend on species, such as dogwoods, to limit the amount of direct solar radiation that reaches the forest floor (Brown 2008). Mycorrhizal fungi play a pivotal role in the biology of orchids and several stages in the orchid's life-cycle, particularly the early stages of seedling development, depend on mycorrhizal fungal symbioses.

Clustered lady's-slipper appears intolerant of disturbances that directly reduce the duff layer and expose or damage the plant's rhizomes (underground stems) or mycorrhizal symbionts. It is usually found in areas that have not been disturbed, or in areas where the disturbance was light or in the distant past. Clustered lady's-slipper orchids appear to tolerate, and in some cases even benefit from, low severity fires. In contrast, high severity fires that eliminate the duff layer or destroy the overstory canopy have been shown to severely impact or kill individuals (Vance 2005).

The overall trend for this species is thought to be declining. In a recent population viability analysis of Oregon occurrences, Thorpe et al. (2010) determined that 59 percent of clustered lady's slipper populations had declined in size and 31 percent fell to zero. They also determined that smaller populations (less than 10 individuals) had a higher rate of extinction compared to larger populations. The primary threat to this species is disturbance that severely alters the light and soil moisture regime at the microsite level. Examples of other threats include: timber harvest activities that remove most of the overstory canopy; soil compaction from equipment and vehicles; high intensity, stand-replacing wildfires; and illegal collection (Vance 2005). Clustered lady's-slipper orchids can also be negatively impacted by dense, homogenous stand conditions where fire has been excluded for over a century (Brown 2008).

Seven occurrences of clustered lady's-slipper, covering approximately 7.6 acres, fall within the Botany analysis area. Of these, five occurrences (covering less than 0.5 acre total) are within treatment units (Table 73). These sites are proposed for habitat enhancement treatments, which include hand thinning of small diameter trees (i.e. those less than 8 inches DBH) in close proximity to orchids and underburning. No occurrences are within any of the proposed noxious weed treatment units.

Table 73. Comparison of Clustered Lady's-Slipper Abundance at the Global, State, Forest, and Project Scale

Species	Global Ranking	Number of Occurrences			
		California	Plumas NF	Keddie Analysis Area	Treatment Units
Cypripedium fasciculatum	G4[1]	348	148	7	5

[1] G4 = apparently secure; factors exist to cause concern, such as limited habitat or population threat (NatureServe 2009)

Quincy lupine (*Lupinus dalesiae)*

This perennial lupine species is known to occur in Plumas County and in isolated occurrences in Sierra and Yuba counties in California. Within this limited range, Quincy lupine is locally abundant. There are currently 255 occurrences documented on the Plumas NF. Outside of the Plumas NF, there are 22 occurrences, all of which occur on lands adjacent to the National Forest.

Quincy lupine is found in a variety of habitats that include undisturbed and disturbed sites (such as old skid trails and road cut banks), openings in chaparral, cismontane woodlands, and mixed conifer forests. Recent visits to old project areas have shown that this species tolerates and even thrives on disturbance;

however the intensity, extent, or frequency of the disturbance associated with these occurrences has not been quantified in a manner that facilitates the development of prescriptions that consistently mimic historical disturbance regimes.

The trend for this plant is stable. Threats include road construction and maintenance; timber harvest, release, and site preparation activities; mining; off-highway vehicle use; and development on private lands. The California Native Plant Society recently lowered the listing status of Quincy lupine (from List 1B to List 4) based on the number of mapped occurrences in the California Fish and Game's California Natural Diversity Database (CNDDB).

Three occurrences of Quincy lupine, covering approximately 45 acres, have been documented within the Keddie Ridge botany analysis area; one occurrence, comprised of six sub-occurrences and covering less than a tenth of an acre, is within proposed treatment units 78 (a and b) and 89 (Table 74). No occurrences are within any of the proposed noxious weed treatment units.

Table 74. Comparison of Quincy Lupine Abundance at the Global, State, Forest, and Project Scale

Species	Global Ranking	Number of Occurrences			
		California	Plumas NF	Keddie Analysis Area	Treatment Units
Lupinus dalesiae	G3[1]	277	255	3	1
[1] G3 = vulnerable to extirpation or extinction; 21 to 80 occurrences, OR 3,000 to 10,000 individuals, OR 10,000 to 50,000 acres					

Plumas alpine-aster (*Oreostemma elatum*)

Plumas alpine-aster occupies wet meadows, fens, and seeps within the upper montane coniferous forests of Plumas, Lassen, and Sierra counties. This perennial plant is known from 17 occurrences in California, 14 of which are located on the Plumas NF (CNDDB 2010). The California Native Plant Society lists Plumas alpine-aster as a 1B.2 species, which indicates that it is fairly endangered in California (CNPS 2010).

Plumas alpine-aster is found between 3,300 and 6,900 feet in elevation. Occurrences, which range in size from 25 square feet to over four acres, are typically found in undisturbed sites that have open overstory canopies and high soil moisture. Threats from management activities include mining, road building, livestock grazing, and recreation activities.

Six occurrences of Plumas alpine-aster, covering approximately 9.4 acres, have been documented within the Keddie Ridge botany analysis area; a small portion (0.05 acre) of two occurrences, fall within proposed treatment units 6 and 11 (Table 75). No occurrences are within any of the proposed noxious weed treatment units.

Table 75. A Comparison of Plumas Alpine-Aster Abundance at the Global, State, Forest, and Project Scale

Species	Global Ranking	Number of Occurrences			
		California	Plumas NF	Keddie Analysis Area	Treatment Units
Oreostemma elatum	G2 [1]	17	14	6	2
[1] G2 = imperiled; 6-20 viable occurrences, OR 1,000 to 3,000 individuals, OR 2,000 to 10,000 acres (NatureServe 2009).					

Environmental Consequences

General Effects on Rare Plant Species

The following provides a discussion of the direct, indirect, and cumulative effects that are applicable to all rare plant species considered in this analysis. A general discussion of cumulative effects (for all action alternatives) on rare plant species is also provided. Species-specific effects are discussed in the section titled "Environmental Consequences: Effects on Specific Rare Plant Species". The effects of the vegetation, fuels, and noxious weed treatments on rare species were similar across all action alternatives; therefore, this discussion is organized to *highlight differences* between the no action alternative and action alternatives A, C, D, and E.

Alternative B (No Action)

Direct Effects

No direct effects are anticipated because no project-related activities would be implemented.

Indirect Effects

Stands would continue to grow and become more dense, resulting in increased shading, duff, fuels accumulation, and canopy closure. These conditions could negatively impact the rare plant species that have been documented within the Botany analysis area by reducing the quality of existing habitat as well as the amount of suitable, but unoccupied habitat. These stand conditions and the continued exclusion of fire would also increase the risk of catastrophic wildfire, which could have detrimental effects on all of the rare species within the Botany analysis area.

Under this alternative, the existing noxious weed infestations would continue to expand along roadsides, in forest openings, along riparian corridors, into meadows, and within other areas of suitable habitat. Noxious weed species pose a serious threat to ecosystem function because of their ability to displace native species, alter nutrient and fire cycles, decrease the availability of forage for wildlife, and degrade soil structure (Bossard et al. 2000). Noxious weed establishment and spread in the Botany analysis area has the potential to negatively affect suitable habitat, not only for rare species, but also for all native plant species.

Alternatives A, C, D, and E (Action Alternatives)

Direct Effects of Vegetation and Fuel Treatments

Direct effects would be avoided or reduced for rare plant species to a level compatible with each species' ecology by incorporating the protection measures for individual species found in Appendix H – Standard Management Requirements and Monitoring.

Direct Effects of Herbicide Treatments

The direct effect of herbicides on rare species is considered negligible due to a combination of factors. First, all of the rare plant occurrences are greater than 0.9 miles from any of the proposed herbicide or fungicide (i.e. borax) treatment locations (Table 76). Second, with the exception of Plumas alpine-aster, the rare plants discussed in this analysis are found in upland habitat types. The herbicide proposed for treatment in these areas is aminopyralid, which is a relatively selective herbicide that affects broadleaf species, particularly those in the sunflower family. Third, the methods proposed for application (wick and backpack) would greatly reduce the possibility of any direct effects on rare and non-target native species. These factors all drastically reduce the risk of direct effects from the proposed herbicide applications.

Table 76. Estimated Distances between Region 5 Forest Service Sensitive Plant Species and Proposed Herbicide Treatments

Sensitive Species	Distance (miles) to nearest:	
	proposed herbicide treatment	proposed Borax treatment
Arabis constancei **(Constance's rock cress)**	4.2	4.2
Cypripedium fasciculatum **(clustered lady's-slipper)**	3.1	4.4
Lupinus dalesiae **(Quincy lupine)**	4.1	4.1
Oreostemma elatum **(Plumas alpine-aster)**	0.9	5.7

The ecological effects of aminopyralid, glyphosate, and borax are discussed in detail in the SERA Risk Assessments (2003a, 2006, 2007) and the HFQLG Final Supplemental EIS (USDA 2003); this analysis tiers to these documents. In general, information regarding the direct effects of the fungicide, the two proposed herbicides, surfactant, and marker dye on rare plant species is almost nonexistent (USDA 2003a).

Both of the proposed herbicides are highly effective at killing target species. Aminopyralid is a selective herbicide that affects target (and some non-target) species by disrupting the plant's metabolism and growth. In contrast, glyphosate is a nonselective herbicide that has the potential to affect both target and non-target plant species by inhibiting or halting growth and disrupting cellular processes (SERA 2003). Although the primary component in borax (i.e. boron) is an essential trace element for terrestrial plants, excessive quantities can lead to adverse effects in plants including chlorosis of leaves, leaf necrosis, and decreased germination (SERA 2003).

The proposed surfactant (i.e. Competitor® or an equivalent formulation) is a modified vegetable oil, which is very unlikely to produce secondary breakdown products that would act as toxins to rare plant species. In addition, the proposed marker dye (i.e. Hi-light® Blue or an equivalent formulation) is a water-soluble dye that contains no listed hazardous substances (SERA 1997) and is unlikely to cause adverse effects on rare plant species.

For the remainder of this analysis, the discussion of effects resulting from herbicide application takes into consideration the effects of the herbicide's active and inert ingredients (the latter of which is water), metabolites, surfactant, and marker dye.

Indirect Effects of Vegetation and Fuel Treatments

The proposed treatments would have a minor but beneficial indirect effect on rare plant species in the Botany analysis area. Implementation of the action alternatives would result in reduced forest canopy and stand density, increased light to the forest floor, and reduced risk of high-intensity wildfire. These conditions would result in larger areas of suitable habitat for rare plant species across the Keddie Ridge Project area.

Noxious weed species are oftentimes classified as "pioneer" species or invaders. Disturbance, whether it is natural (i.e. a lightning-caused fire) or associated with project activities, often creates ideal conditions for weed introduction and establishment. Although rare plant species would be buffered from the direct effects of project activities, there is still the risk of an indirect effect from weed invasion from adjacent areas that have been disturbed. Under Alternatives A and C this risk is greatly reduced through implementation of the proposed noxious weed treatments.

Indirect Effects of Herbicide Treatments

The indirect effects of herbicides on rare plant species can include accidental spills, spray drift, surface runoff, or a combination of these factors. In general, the primary hazard to non-target terrestrial plant species is herbicide drift, which can be minimized by implementing the following design features: (1) avoidance through buffers, (2) spraying when the wind is absent or blowing away from the plants, and/or (3) using an application method other than spraying (USDA 2003a).

Applications of glyphosate in 0 to 5 mile per hour (mph) winds using a backpack sprayer have demonstrated that droplets can drift as far as 23 feet; applications made in a 15 mph wind have the potential to drift up to 68 feet (SERA 2003). Based on these calculations, the geographic distance between rare species and the proposed herbicide treatments (Table 76) is sufficient to significantly reduce the risk of indirect effects due to drift.

Another potential indirect effect on rare plant species would be if an herbicide treatment were to negatively impact pollinator species. To quantify the potential impact on pollinator species, a scenario was analyzed to examine the effect of directly spraying a honey bee (assuming 100 percent absorption and over 50 percent of the body surface) with both of the proposed herbicides (SERA 2003, 2007). The level of risk was determined using the "Hazard Quotient." A Hazard Quotient less than "1" is considered to be a low risk. The results of this analysis, which are presented in Table 77, indicate that there would be a low risk to honey bees using the chemicals, rates, and volumes proposed under alternatives A and D.

Table 77. Analysis of a Scenario Involving 100 Percent Absorption of Aminopyralid and Glyphosate by a Honey Bee [Data from SERA Risk Assessments (2003, 2007)]

Herbicide Scenario (100% absorption)	Hazard Quotient
Aminopyralid	0.02
Glyphosate	0.6

There has also been some concern regarding the toxicity of surfactants on terrestrial insects. This is primarily due to the effective spreading ability of these surfactants, which may amount to the physical effect of drowning (rather than any toxicological effects). Studies have indicated that the effect on terrestrial insects is highly dependent upon the dose (Bakke 2007). Surfactants are usually applied at very low rates and, because they are very effective, are usually not applied at high spray volumes (Bakke 2007); therefore, it is unlikely that insects would be exposed to the rates and doses of concern presented in the literature.

Under alternatives A and D, there would be a low risk that the proposed herbicides or surfactant would cause widespread effects on terrestrial insects due to (1) the need for a relatively high dose for a lethal effect, and (2) the fact that individual insects, rather than entire colonies or nests, would most likely be impacted (Bakke 2007).

Indirect Effects of Borax Treatments

The SERA risk assessment for borax indicates that there is a negligible risk of borax exposure to non-target plant species, even when applied at the maximum application rate used by the Forest Service (SERA 2006). In all of the exposure scenarios for terrestrial plants, including pesticide-sensitive species, the level of risk was found to be low (that is, a Hazard Quotient of less than one).

All Action Alternatives: Cumulative Effects on Rare Plant Species

The effects of past activities on rare plant species in the Botany analysis area are largely unknown. On the Plumas NF, rare plant surveys did not begin until the early 1980s. In many cases, even when project-level surveys were conducted, there is very little documentation that describes whether past projects avoided or protected rare plant species during project implementation. In addition to these unknowns, changes have been made to the Plumas NF Sensitive species list. Therefore, in order to incorporate the contribution of past activities into the cumulative effects of the proposed Keddie Ridge Project, this analysis uses the current abundance and distribution of rare plant species as a proxy for the impacts of past actions.

Over the past 30 years, the landscape in the Botany analysis area has experienced high levels of past activity and, consequently, high levels of past disturbance. For those species that occupy open habitats and are tolerant of some level of disturbance, it is possible that past activities in the Botany analysis area have had a beneficial effect by creating openings and areas of suitable habitat across the landscape. However, these activities have also created a highly disturbed landscape, which has increased the susceptibility to noxious weed introduction and spread and increased the overall risk to native plant communities and rare species. The data presented in Figure 21was used as a contextual framework for the analysis of cumulative effects; it presents the proportion of occurrences (both in California and on the

Plumas NF) that have the potential to be affected by the proposed treatments. Overall, less than 25 percent of the known rare plant occurrences fall within the Botany analysis area and less than 15 percent fall within proposed treatment units. Under all of the action alternatives, negative cumulative effects are minimized through implementation of species-specific design criteria.

If existing management guidelines (such as field surveys, protection of known rare plant locations, and implementation of noxious weed standard management requirements) remain in place, the effects of future projects are likely to be minimal or similar to those described in this analysis. Ongoing activities, such as woodcutting, hunting, and dispersed recreation activities, are not likely to make a significant impact on rare plant species; however, these activities may act as vectors for weed spread.

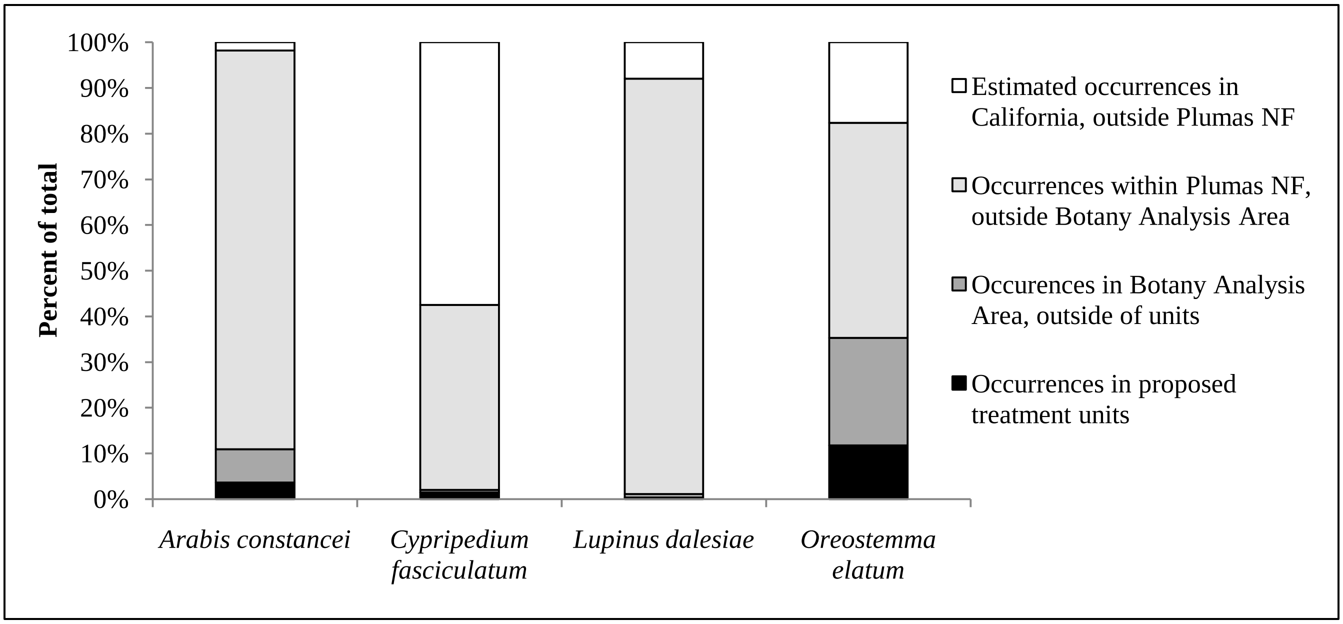

Figure 21. The Percentage of Total Known Occurrences (in California) Potentially Impacted by the Proposed Keddie Ridge Treatments

Effects on Specific Rare Plant Species

The following section provides a discussion of the direct, indirect, and cumulative effects specific to the four Sensitive species that are within the proposed treatment units. These effects are in addition to those discussed in the sections above. The effects of the vegetation, fuels, and noxious weed treatments on rare species were similar across all action alternatives; therefore, this discussion is organized to *highlight differences* between the no action alternative and the action alternatives A, C, D, and E.

Constance's Rock Cress (*Arabis constancei)*

Alternative B – No Action Alternative

Direct Effects

No direct effects are anticipated because no project-related activities would occur.

Indirect Effects

Under the no action alternative, small trees would not be hand thinned within the two Constance's rock cress occurrences. This could have two possible indirect effects on the species: (a) it may reduce the amount of suitable habitat within occurrences and (b) it could increase the risk and severity of wildfire.

The exclusion of fire for over a century within the rock cress occurrences has resulted in scattered areas with high concentrations of small conifer trees. Conifers on serpentine have been shown to modify the physical characteristics of their immediate surroundings by increasing the soil depth, organic matter, calcium to magnesium ratio, and lowering the pH (Chiarucci and DeDominicis 1995, Barton and Wallenstein 1997). These types of changes can result in the exclusion of rare serpentine species such as Constance's rock cress, which is most commonly found in open, sparsely vegetated areas with shallow serpentine soils. Under this alternative, areas with high concentrations of small trees, which have greater canopy cover, increased duff depth, and potentially altered soil characteristics, will continue to be marginal habitat for this rare species.

Although many serpentine species rely on fire to maintain the vegetative characteristics of their habitat, very few of the serpentine endemic plants in California are believed to be fire-dependent (Safford and Harrison 2004). In fact, many rare serpentine species are thought to be restricted to these harsh soils as a result of their intolerance to frequent or high intensity fires (Safford and Harrison 2008). Constance's rock cress appears to be no exception; monitoring data suggest that this species is tolerant of low intensity fire, but is intolerant of high intensity fire (USDA 2008c). Under the no action alternative, the risk of negative impacts from high-severity wildfire would not be reduced.

Cumulative Effects

Over the past 100 years, Constance's rock cress has undoubtedly lost individuals and areas of suitable habitat as a result of ground disturbing activities such as gold and gravel mining, timber harvest, road construction, and recreational off-highway vehicle use. Constance's rock cress has been on the Plumas NF Sensitive species list since at least 1979; therefore it is expected that projects implemented over the past 30 years would have avoided or mitigated negative effects to known occurrences. A review of past projects (appendix F) indicates that this has generally been the case. Five of the six occurrences in the Botany analysis area fall within the boundary of a past timber sale and all were avoided during project implementation. One exception to this was a mining operation expansion that occurred in the early 1980's. This project likely impacted both individuals and areas of suitable habitat within this occurrence, which occurs in the Botany analysis area but outside of the proposed Keddie Ridge Project units.

Although there may be some negative indirect effects from the no action alternative, the overall cumulative effects are expected to be minor. Even though existing occurrences would not be enhanced or protected from high-severity wildfire, the effects from the no action alternative would not be significant enough to reduce the overall viability of Constance's rock cress.

The effects of future projects on Constance's rock cress would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Action Alternatives (A, C, D, and E)

Direct Effects

No direct effects are anticipated from mechanical thinning, group selection harvest, mastication, or noxious weed treatment because these activities will be prohibited within Constance's rock cress occurrences. The direct effects to Constance's rock cress from hand thinning are expected to be minimal because (a) very few individuals grow within the dense clusters of trees that are proposed for thinning and (b) all slash will be piled at a sufficient distance to protect individual plants and the seedbank from excessive heat. Some individual plants may be directly impacted from the prescribed fire treatments; however monitoring data collected before and after prescribed burning suggest that this species is tolerant of low to moderate intensity fire (USDA 2008c).

Indirect Effects

The proposed hand thinning and prescribed fire treatments could increase the amount of suitable habitat within Constance's rock cress occurrences by opening up the overstory canopy, reducing the duff layer, and thinning dense clusters of trees. Studies have shown that conifers can alter the physical characteristics of serpentine soils and make them less suitable for serpentine endemic plants (Chiarucci and DeDominicis 1995, Barton and Wallenstein 1997).

Although fires on serpentine tend to be smaller, less frequent, and less severe, periodic fire is believed to be an important factor for maintaining the vegetative characteristics of many serpentine habitats (i.e. Arabas 2000). Therefore, the reintroduction of prescribed fire will likely have a beneficial impact on Constance's rock cress habitat. Thinning the dense clusters of small trees prior to burning will reduce the fire intensity as well as the threat of future high-severity wildfires; both of these actions will reduce the potential for long-term negative impacts on Constance's rock cress.

The mechanical thinning proposed within Treatment Unit 71 will have a negligible indirect effect on Constance's rock cress habitat. The habitat within this unit is considered to be marginal for Constance's rock cress, due to historic rock deposition that has occurred over an older serpentine substrate. Due to the low quality of the serpentine substrate, thinning the surrounding stands will likely not create additional areas of suitable habitat for Constance's rock cress.

While serpentine habitats tend to be less invaded by non-native species than other habitat types, treatment activities still increase the risk of noxious weed introduction and spread within these occurrences (Harrison 1999). The control measures proposed under alternatives A and D will greatly reduce the risk of invasion into these habitats and the potential impact to Constance's rock cress. The indirect effect of herbicide treatments on Constance's rock cress occurrences would be negligible because the closest treatment site is over four miles away.

Cumulative Effects

This species has undoubtedly lost individuals and areas of suitable habitat over the past 100 years as a result of ground disturbing activities such as mining, timber harvest, road construction, and recreational off-highway vehicle use. Constance's rock cress has been on the Plumas National Forest Sensitive species list since at least 1979; therefore it is expected that projects implemented over the past 30 years would have avoided or mitigated negative effects to known occurrences. A review of past projects (appendix F) indicates that this has generally been the case. Five of the six occurrences in the Botany analysis area fall within the boundary of a past timber sale and all were avoided during project implementation. One exception to this was a mining operation expansion that occurred in the early 1980’s. Individuals and areas of suitable habitat were likely impacted within this occurrence, which occurs in the Botany analysis area but outside of the proposed Keddie Ridge Project units.

The two occurrences within the proposed treatment units represent approximately four percent of all known occurrences in California (Figure 21). Less than one percent (0.3 percent) of estimated suitable habitat for Constance’s rock cress has the potential to be impacted by the proposed project activities (i.e. falls within a treatment unit). It is expected that implementation of the action alternatives will not reduce the viability of Constance’s rock cress due to (a) this relatively small proportion of occurrences and suitable habitat impacted; (b) the low intensity of the proposed treatments; and (c) the potential for positive indirect effects. Overall, the cumulative effects from the proposed activities are expected to be minor.

The effects of future projects on Constance’s rock cress would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Summary of determinations for Constance’s rock cress

No Action Alternative (B)

The no action alternative may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for *Arabis constancei* (Constance’s rock cress). Under this alternative, direct effects to individuals will be avoided; therefore this determination is based on the potential for long-term impacts to areas of suitable habitat.

Action Alternatives (A, C, D, and E)

The Keddie Ridge Project action alternatives (A, C, D, and E) may affect individuals, but are not likely to result in a trend toward Federal listing or loss of viability for *Arabis constancei* (Constance’s rock cress). This determination is based on the potential for impacts to individuals and areas of suitable habitat.

Cypripedium fasciculatum **(clustered lady’s-slipper)**

Alternative B – No Action Alternative

Direct Effects

No direct effects are anticipated because no project-related activities would occur.

Indirect Effects

Under this alternative, the five clustered lady’s-slipper occurrences and their surrounding stands would not be treated. This could indirectly affect the species over the long-term by reducing the quality of occupied and unoccupied habitat and by increasing the risk of extirpation from high severity wildfires.

Fire has been excluded from most of the clustered lady's-slipper orchid sites within the Botany analysis area for over a century, which has resulted in densely forested stands with closed overstory canopies. Dense overstory canopy can negatively impact the abundance of understory species such as dogwood, which have been shown to have indirect impacts on the quality of orchid microsites (Brown 2008). In addition, dense clusters of small conifers can compete with clustered lady's-slippers for limited understory resources such as space, light, and water (Brown 2008). Under the no action alternative, stands would continue to become dense and could result in a decrease in habitat quality for clustered lady's slipper over the long-term.

The no action alternative would not implement treatments designed to reduce the risk of high-severity wildfires within clustered lady's-slipper orchid sites. An analysis of clustered lady's-slipper populations in northern California determined that over 75 percent of sites had an elevated risk of extirpation due to high intensity wildfire (Vance 2005). Research has also suggested that increased summer drought from climate change could increase both the frequency and severity of wildfires throughout the western United States (e.g. Whitlock et al. 2003, Marlon et al. 2009). These two factors (i.e. vulnerability to extinction from high-intensity fire and increased likelihood of wildfires) elevate the risk to clustered lady's slipper occurrences within the Keddie Ridge Project area. Severe wildfires could not only negatively impact individual plants, but could also reduce the availability of suitable habitat by removing the overstory canopy and adversely impacting soil conditions.

Cumulative Effects

Clustered lady's-slipper has likely lost individuals and a considerable amount of suitable habitat over the last 100 years due to human activities related to mining, logging, road building, fire suppression, and homesteading (Kaye and Cramer 2005). These activities, to one extent or another, have resulted in a reduction in canopy cover, modification of stand dynamics, alteration in fire frequency and intensity, and change in microclimate conditions.

Clustered lady's-slipper has been designated as a Plumas NF Sensitive or Special Interest species since the early 1980's. A review of past projects (appendix F) indicates that protection measures for this species were included when occurrences were known at the time of implementation. For example, of the four occurrences that fall within the boundary of a past timber harvest, only one was known (and consequently protected) at the time of project implementation; the remaining three occurrences, which were discovered only recently (after 2006), were not protected. This underscores the fact that many of the management activities that have occurred within the Botany analysis area have potentially impacted clustered lady's-slipper occurrences and areas of suitable habitat.

Overall, the cumulative effects from the no action alternative are expected to be negligible to minor, primarily because the direct and indirect effects are expected to be minor. Although existing occurrences would not be enhanced or protected from high-severity wildfire, the no action alternative would not significantly reduce the viability of clustered lady's-slipper.

The effects of future projects on clustered lady's-slipper would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Action Alternatives (A, C, D, and E)

Direct Effects

No direct effects are anticipated from mechanical thinning, group selection harvest, mastication, or noxious weed treatment because these activities will be prohibited within clustered lady's-slipper orchid sites. The direct effects to clustered lady's-slipper from hand thinning are expected to be minor because individual plants will be avoided during implementation and hand piles will be placed at a sufficient distance from plants to ensure that radiant heat will not impact individuals or the surrounding duff layer. Some individual plants may be directly impacted from prescribed fire treatments; however surface fuels will be manipulated (i.e. pulled back) prior to treatment in order to reduce the fire intensity and consumption of the duff layer. Clustered lady's-slipper orchids appear to tolerate, and in some cases even benefit from, low severity fires; however their response has been shown to be highly dependent upon the characteristics of the site, as well as the intensity and duration of the burn.

Indirect Effects

The proposed hand thinning and prescribed fire treatments would increase the habitat quality within existing clustered lady's-slipper occurrences by: (a) increasing the amount of light that reaches understory species such as dogwood, which are thought to indirectly impact the quality of orchid microsites, and (b) removing small conifer trees (less than 8 inches DBH) that may compete with orchids for limited understory resources such as space, light, and water (Brown 2008). Under all of the action alternatives, hand thinning treatments within orchid sites are designed to maintain the essential components of the orchid's microsites; these include sufficient overstory canopy cover to reduce direct solar radiation to individual plants, decayed down logs and standing snags, an adequate duff layer, and undisturbed soils. Over the long-term, the proposed thinning treatments would also reduce the risk of negative impacts from high-severity wildfires, which could affect both individuals and areas of suitable habitat.

Five of the clustered lady's slipper occurrences are within units where mechanical thinning and group selection harvest is proposed. Although all of the known occurrences will be designated as control areas where these activities will be excluded, some areas of unoccupied suitable habitat may be negatively impacted by implementation of the action alternatives. In the short-term, areas where the overstory canopy is completely removed (i.e. in group selection units), would become unsuitable habitat for clustered lady's slippers.

The indirect effect of implementing the proposed herbicide treatments (under alternatives A and D) would be negligible because the closest treatment site is over three miles away (Table 76). While the proposed vegetation treatments will increase the risk of noxious weed introduction and spread into orchid sites, the control measures proposed under alternatives A and D will reduce the risk of invasion into these habitats and the potential impact to clustered lady's-slipper orchids.

Cumulative Effects

Clustered lady's-slipper has likely lost individuals and a considerable amount of suitable habitat over the last 100 years due to human activities related to mining, logging, road building, fire suppression, and homesteading (Kaye and Cramer 2005). These activities have, to one extent or another, resulted in a reduction in canopy cover, modification of stand dynamics, alteration in fire frequency and intensity, and change in microclimate conditions.

Clustered lady's-slipper has been designated as a Plumas NF Sensitive or Special Interest species since the early 1980's. A review of past projects (appendix F) indicates that protection measures for this species were included when occurrences were known at the time of implementation. For example, of the four occurrences that fall within the boundary of a past timber harvest, only one was known (and consequently protected) at the time of project implementation; the remaining three occurrences, which were discovered only recently (after 2006), were not protected. This underscores the fact that many of the management activities that have occurred within the Botany analysis area have potentially impacted clustered lady's-slipper occurrences and areas of suitable habitat.

The five occurrences within the treatment units represent less than four percent of all known occurrences on the Plumas NF (

Figure 21). It is expected that implementation of the action alternatives will not reduce the viability of clustered lady's-slipper due to (a) this relatively small proportion of occurrences with the potential to be impacted; (b) the low intensity of the proposed treatments; and (c) the potential for positive indirect effects. Overall, the cumulative effects from the proposed activities are expected to be minor.

The effects of present and future projects on this species would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Summary of Determinations for Clustered Lady's-slipper

No Action Alternative (B)

The no action alternative may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for *Cypripedium fasciculatum* (clustered lady's-slipper). Under this alternative, direct effects to individuals will be avoided; therefore this determination is based on the potential for long-term impacts to areas of suitable habitat.

Action Alternatives (A, C, D, and E)

The Keddie Ridge Project action alternatives (A, C, D, and E) may affect individuals, but are not likely to result in a trend toward Federal listing or loss of viability for *Cypripedium fasciculatum* (clustered lady's-slipper). This determination is based on the potential for impacts to individuals and areas of suitable habitat.

***Lupinus dalesiae* (Quincy lupine)**

Alternative B – No Action Alternative

Direct Effects

No direct effects are anticipated because no project-related activities would occur.

Indirect Effects

Quincy lupine may be negatively affected by the no action alternative. This species is most commonly associated with open habitats, many of which have been previously disturbed. Although Quincy lupine has been found in undisturbed sites, it has not been documented in dense forest stands with high overstory canopy cover. Under the no action alternative, the number of trees within stands would continue to increase, resulting in areas with greater canopy cover, reduced light to the understory, and increased duff and litter deposition. Over time, this would decrease the habitat quality within existing Quincy lupine sites and result in a loss of suitable habitat for this species across the landscape.

Cumulative Effects

The ability of Quincy lupine to colonize both previously disturbed and undisturbed sites, and tolerate and even thrive on disturbance, suggests that this species may have benefited from past management activities that created open conditions and increased light reception to the understory. The Quincy lupine occurrences within the Keddie Ridge Project area are found along road cuts, in old skid trails, previous timber sales, and within the perimeter of large, historic fires.

The three occurrences within the Botany analysis area represent one percent of all known occurrences on the Plumas NF and in California; the one occurrence within the proposed treatment units represents less than 0.5 percent of all known occurrences (Figure 21). Areas of suitable, but unoccupied habitat, exist in just under half (42 percent) of the proposed treatment units. Because of Quincy lupine's ability to tolerate a broad range of habitat conditions, this area represents only a small fraction (less than one percent) of the total estimated area of suitable habitat across the Plumas NF.

There would be no direct effect to Quincy lupine under the no action alternative; however the potential for indirect effects could result in negative cumulative effects over time. Under this alternative, additional areas of suitable habitat would not be created and the habitat within existing occurrences would not be enhanced. The effects of present and future projects on this species would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Action Alternatives (A, C, D, and E)

Direct Effects

Quincy lupine is a perennial herb that is found in undisturbed and disturbed sites (i.e. old skid trails and road cut banks). Monitoring has demonstrated that this species tolerates and even thrives on disturbance. Individuals have often been found occupying areas that were previously disturbed by mechanical thinning activities or along road cut banks. Recent monitoring within group selection units found that the number of individuals increased following treatment, even when all of the overstory trees were removed and the plants were situated in the middle of a skid trail (USDA 2008a).

Some individual plants may be directly impacted by the hand thinning and prescribed fire treatments proposed in Units 78a, 78b, and 89. Pile burning may also impact individuals or the soil seed bank if located underneath or in close proximity to the pile (Korb et al. 2004). Overall, the likelihood of negative direct effects is considered low based on (a) the low intensity of the proposed treatments; (b) the positive response of Quincy lupine to disturbance; and (c) the small, scattered locations of Quincy lupine, which are found in openings where thinning activities are unlikely to take place.

Indirect Effects

The proposed project activities are expected to have a beneficial indirect effect on Quincy lupine. This species is most commonly associated with open habitats; it is not found under dense forest canopies. As mentioned above, Quincy lupine has been shown to readily colonize disturbed sites such harvest units, skid trails, and old roads. Past observations also demonstrate that populations respond favorably to both thinning and prescribed fire treatments. Based on these factors, the proposed treatments are expected to improve the habitat quality within existing sites and to increase the amount of suitable habitat for Quincy lupine across the landscape.

The indirect effect of implementing the proposed herbicide treatments would be negligible because the closest treatment site is over four miles away (Table 76). The proposed vegetation treatments will increase the risk of noxious weed introduction and spread into disturbed sites; however the control measures proposed under alternatives A and D will reduce the risk of invasion into these habitats and the potential impact to Quincy lupine individuals and potential habitat.

Cumulative Effects

The ability of Quincy lupine to colonize both previously disturbed and undisturbed sites, and tolerate and even thrive on disturbance, suggests that this species may have benefited from past management activities that created open conditions and increased light reception to the understory. The Quincy lupine occurrences within the Keddie Ridge Project area are found along road cuts, in old skid trails, previous timber sales, and within the perimeter of large, historic fires.

The three occurrences within the Botany analysis area represent one percent of all known occurrences on the Plumas NF and in California; the one occurrence within the proposed treatment units represents less than 0.5 percent of all known occurrences (

Figure 21). Areas of suitable, but unoccupied habitat, exist in just under half (42 percent) of the proposed treatment units. Because of Quincy lupine's ability to tolerate a broad range of habitat conditions, this area represents only a small fraction (less than one percent) of the total estimated area of suitable habitat across the Plumas NF.

Overall, the cumulative effects to this species are anticipated to be beneficial. Although implementation of the action alternatives may have some direct impacts on individuals, these effects will likely not be severe enough to negatively impact the long-term viability of Quincy lupine. This is based on the small percentage of sites with potential to be directly impacted, the species' high tolerance to disturbance, and the creation of additional areas of suitable habitat through implementation of the proposed treatments.

The effects of present and future projects on this species would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Summary of Determinations for Quincy Lupine

No Action Alternative (B)

The no action alternative may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for *Lupinus dalesiae* (Quincy lupine). Under this alternative, direct effects to individuals will be avoided; therefore this determination is based on the potential for long-term impacts to areas of suitable habitat.

Action Alternatives (A, C, D, and E)

The Keddie Ridge Project action alternatives (A, C, D, and E) may affect individuals, but are not likely to result in a trend toward Federal listing or loss of viability for *Lupinus dalesiae* (Quincy lupine). This determination is based on the potential for impacts to individuals and areas of suitable habitat.

Oreostemma elatum **(Plumas alpine-aster)**

Alternative B – No Action Alternative

Direct Effects

No direct effects are anticipated because no project-related activities would occur.

Indirect Effects

The no action alternative is expected to have a negligible effect on Plumas alpine-aster. This species grows in wet meadows and small spring-fed forest openings where high soil moisture levels during the fire season and the dominance of fine fuels (i.e. grass-like species) greatly reduce the likelihood of high-severity fire (Dwire and Kauffman 2003). Based on this, the lack of treatments in adjacent stands is not expected to significantly alter the future wildfire risk or intensity within Plumas alpine-aster occurrences or areas of unoccupied suitable habitat.

Cumulative Effects

Plumas alpine-aster has likely lost individuals and a considerable amount of suitable habitat over the past 100 years due to land use activities such as water diversions, habitat type conversion (i.e. meadow to annual grassland), intense grazing by domestic livestock, and construction of roads and trails. This species was added to the Plumas NF Sensitive species relatively recently in 1998; therefore it is unknown whether projects implemented more than 12 years ago avoided or mitigated negative effects to known occurrences. With the exception of some land use activities (such as off highway vehicle use, fire suppression, etc.), protection measures for meadows have generally been in place for nearly 25 years (USDA 1988). In addition, none of the past projects (described in appendix F) occurred in or near the Plumas alpine-aster occurrences in the Botany analysis area. Based on these two factors, it is likely that the six Plumas alpine-aster occurrences have received little impact from management activities in the past few decades.

There would be no cumulative effects from the no action alternative because the direct and indirect effects are expected to be negligible. The effects of future projects on Plumas alpine-aster would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Action Alternatives (A, C, D, and E)

Direct Effects

No direct effects will occur because the two Plumas alpine-aster occurrences will be flagged for avoidance.

Indirect Effects

The indirect effects from the action alternatives are anticipated to be negligible. Plumas alpine-aster is found in wet meadows and small spring-fed openings within forested habitats. These types of habitats differ from their surrounding uplands in moisture regime, microclimate, and vegetative composition (Pettit and Naiman 2007). In general, high soil moisture levels and the dominance of grass-like species (i.e. fine fuels) greatly reduce the risk of high-severity wildfire within these habitats. Based on this, the hand thinning and underburning treatments in adjacent stands are not expected to significantly alter the future wildfire risk or intensity within Plumas alpine-aster occurrences or unoccupied suitable habitat.

Positive effects of the proposed thinning treatments may include increased water percolation and groundwater, which could slightly increase the water availability within adjacent meadow habitats where Plumas alpine-aster is found. Occurrences and suitable habitat for Plumas alpine-aster will be avoided during project implementation; therefore the proposed activities are not expected to negatively affect the timing or hydrologic regime within areas of suitable habitat.

The indirect effect of implementing the proposed herbicide treatments (under alternatives A and D) would be negligible because the closest treatment site is 0.9 miles away (Table 76). Meadows and seeps are highly susceptible to invasion from noxious weed species that thrive under wet conditions, such as Canada thistle (*Cirsium arvense*). While the proposed treatments may increase the risk of noxious weed introduction and spread into these areas; the control measures proposed under alternatives A and D will reduce the risk of invasion into these habitats and the potential impact to Plumas alpine-aster individuals and potential habitat.

Cumulative Effects

Plumas alpine-aster has likely lost individuals and a considerable amount of suitable habitat over the past 100 years due to land use activities such as water diversions, habitat type conversion (i.e. meadow to annual grassland), intense grazing by domestic livestock, and construction of roads and trails. This species was added to the Plumas NF Sensitive species relatively recently in 1998; therefore it is unknown whether projects implemented more than 12 years ago avoided or mitigated negative effects to known occurrences. With the exception of some land use activities (such as off highway vehicle use, fire suppression, etc.), protection measures for meadows have generally been in place for nearly 25 years

(USDA 1988). In addition, none of the past projects (described in Appendix F) occurred in or near the Plumas alpine-aster occurrences in the Botany analysis area. Based on these two factors, it is likely that the six Plumas alpine-aster occurrences have received little impact from management activities in the past few decades.

The six occurrences in the Botany analysis area represent 35 percent of the Plumas alpine-aster occurrences in California; the two occurrences within the treatment units represent approximately 12 percent of all known occurrences (Figure 21). All of these occurrences will be avoided during implementation of the action alternatives. In addition, areas of suitable habitat will be protected through implementation of best management practices (BMPs). Based on these protection measures, as well as the negligible direct and indirect effects to Plumas alpine-aster, no adverse cumulative effects are anticipated from implementation of the action alternatives.

The effects of future projects on Plumas alpine-aster would likely be minimal or similar to those described in this analysis if existing management guidelines (such as field surveys, protection of known rare species locations, and noxious weed standard management requirements) remain in place.

Summary of Determinations for Plumas Alpine-aster

No Action Alternative (B)

The no action alternative (B) will not affect *Oreostemma elatum* (Plumas alpine-aster). This determination is based on the negligible direct and indirect effects to individuals and areas of suitable habitat.

Action Alternatives (A, C, D, and E)

The Keddie Ridge Project action alternatives (A, C, D, and E) will not affect *Oreostemma elatum* (Plumas alpine-aster). This determination is based on the negligible direct and indirect effects to individuals and areas of suitable habitat.

Summary of Effects

The effects presented below are based on professional experience and judgment; the existing condition of botanical resources within the analysis area, and the potential impacts of the alternatives.

Alternative B (No Action)

- The no action alternative may affect individuals, but is not likely to result in a trend toward Federal listing or loss of viability for *Arabis constancei* (Constance's rock cress), *Cypripedium fasciculatum* (clustered lady's-slipper), and *Lupinus dalesiae* (Quincy lupine). Under this alternative, direct effects to individuals will be avoided; therefore this determination is based on the potential for long-term impacts to areas of suitable habitat.
- Alternative B (no action) will not affect *Oreostemma elatum* (Plumas alpine-aster). This determination is based on the negligible direct and indirect effects to individuals and areas of suitable habitat.
- Alternative B (no action) will not affect any other Region 5 Sensitive plant species or any Threatened, Endangered, or Candidate plant species. This determination is based on the absence of suitable habitat

within the project area for these species and the lack of individuals known or expected to occur within the project area.

Action Alternatives (A, C, D, and E)

- The Keddie Ridge Project action alternatives (A, C, D, and E) may affect individuals, but are not likely to result in a trend toward Federal listing or loss of viability for *Arabis constancei* (Constance's rock cress), *Cypripedium fasciculatum* (clustered lady's-slipper), and *Lupinus dalesiae* (Quincy lupine). This determination is based on the potential for impacts to individuals and areas of suitable habitat.
- The Keddie Ridge Project action alternatives (A, C, D, and E) will not affect *Oreostemma elatum* (Plumas alpine-aster). This determination is based on the negligible direct and indirect effects to individuals and areas of suitable habitat.
- The action alternatives (A, C, D, and E) will not affect any other Region 5 Sensitive plant species or any Threatened, Endangered, or Candidate plant species. This determination is based on the absence of suitable habitat within the project area for these species and the lack of individuals known or expected to occur within the project area.

Compliance with the Forest Plan and Other Direction

All of the alternatives are consistent with the Forest Plan and other direction. Under these alternatives, sensitive plant species are protected as needed to maintain viability.

Noxious Weeds

Introduction

In 2003, the United States Forest Service identified invasive species as one of four critical threats to the nation's ecosystems (Bosworth 2003). Noxious weed species pose a significant threat to ecological function due to their ability to displace native species, alter nutrient and fire cycles, decrease the availability of forage for wildlife, and degrade soil structure (Bossard et al. 2000). Noxious weed species have the potential to affect native plant species indirectly through allelopathy (the production and release of plant compounds that inhibit the growth of other plants) (Bais et al. 2003), as well as through direct competition for nutrients, light, and water (Bossard et al. 2000). Noxious weed infestations can also reduce the recreational or aesthetic value of native habitats.

Forest management activities, such as those associated with timber harvest, can contribute to the introduction and spread of noxious weed species by creating suitable environmental conditions for establishment and by acting as vectors for spread. The following section provides a discussion of the risk associated with noxious weed introduction and spread as a result of the proposed Keddie Ridge project. A complete assessment of noxious weed risk is appended to the Keddie Ridge Hazardous Fuels Reduction Project: Biological Evaluation of Potential Effects to Threatened, Endangered, and Sensitive Plant Species (USDA 2011f), which is located in the project record and incorporated by reference.

Analysis Framework: Statute, Regulatory Environment, Forest Plan, and Other Direction

Federal Acts and Orders

Executive Order 13112 (1999)**-** directs federal agencies to prevent the introduction of invasive species; detect and respond rapidly to control such species; and to minimize the economic, ecological, and human health impacts from invasive species on NFS lands.

Forest Service Manual (FSM) Direction

FSM Section 2081.03 **-** directs the U.S. Forest Service to prevent the introduction and establishment of noxious weeds; contain and suppress existing weed infestations; and to educate and cooperate with agencies, land owners, land managers, and members of the public to control weeds. It also requires a weed risk assessment for any proposed ground disturbing activities and calls for the incorporation of noxious weed control measures into any project that has a moderate to high risk of introducing or spreading noxious weeds.

Forest Plan

Plumas NF Land Management Plan (USDA 1988, 1999a, 2004b): The Herger-Feinstein Quincy Library Group (HFQLG) Forest Recovery Act Final Environmental Impact Statement (USDA 2003a) and the 2004 Record of Decision on the Sierra Nevada Forest Plan Amendment (SNFPA) Final Supplemental EIS (USDA 2004b) amended the management direction in the Forest Plan to address management of noxious weeds and invasive exotic (nonnative) species.

The HFQLG EIS provides direction for noxious weed and invasive exotic weed management; this direction is to “manage National Forest System lands so that management activities do not introduce or spread noxious or invasive exotic weeds.” The HFQLG EIS also provides guidelines to follow during project planning and implementation. These guidelines are included as standard management requirements in Appendix H of this document.

The Record of Decision (ROD) for the 2004 SNFPA established goals for noxious weed management using an integrated weed management approach according to the priority set forth in Forest Service Manual 2081.2. The three priorities include:

1. Prevent the introduction of new invaders.
2. Conduct early treatment of new infestations.
3. Contain and control established infestations.

Provisions for implementing these goals are embodied in the noxious weed management standards and guidelines of the SNFPA 2004 Record of Decision.

Effects Analysis Methodology

Geographic Area Evaluated

The geographic area used to analyze the effects to noxious weeds is referred to as the “Botany analysis area”; it encompasses approximately 64,000 acres and consists of all proposed treatment units, including access roads to the treatment units, and the area within one mile of the treatment unit boundaries. This area was selected to focus the analysis on weed species and infestations with the highest potential for impacts within the project area. In general, weed infestations located in close proximity to proposed treatment units and access routes increase the probability of spread into treated areas as well as other parts of the Forest.

Methodology

The analysis of effects for noxious weeds followed a process similar to that described under the Botanical Resources section of this document. Field surveys were conducted within all of the proposed units and data were collected that described the spatial extent of infestations and the potential options for treatment.

The risk of noxious weed spread or introduction was evaluated for each proposed unit using the following factors: (a) amount of soil disturbance associated with the proposed project activities; (b) species invasiveness; (c) proximity to the proposed units; (d) proportion of infestations proposed for treatment; and (e) the effectiveness of the weed treatment measures. In general, a high risk was assigned based on the presence of weed infestations within a proposed unit; a high level of invasiveness; a large amount of soil disturbance associated with the proposed activities (i.e. group selections); and a lack of effective weed treatments.

Indicator Measures

The indicator measures used to compare the effects across the alternatives were: (a) the amount of soil disturbance associated with the proposed project activities; (b) the number and acres of weed sites treated; (c) the effectiveness of the proposed control treatment methods; and (d) the overall risk of noxious weed introduction and spread.

Assumptions

Recent reconnaissance surveys of noxious weed sites within the Botany analysis area suggest that many infestations have spread beyond their originally mapped boundaries; for example, within one proposed weed treatment unit, infestations increased from 2.4 acres to an estimated 4.4 acres over a period of eight years (Coppoletta, personal observation, 2010). To obtain an estimate of the amount of spread that could occur prior to project implementation, the scientific literature was reviewed and general rates of spread were estimated for each species (e.g. Roche 1992, Nuzzo 1997). These values were used to obtain an average rate of spread, which was then applied as a buffer to existing noxious weed polygons within the Botany analysis area. Consequently, all of the noxious weed treatment acres presented in this document represent the maximum area proposed for treatment and take into account the projected amount of spread that may occur prior to project implementation (i.e. over a period of two to three years).

Affected Environment

Five invasive species of high management concern have been documented within the Botany analysis area. These weed species, which are known from roughly 118 locations, range in size from five square feet to over 25 acres. Table 78 lists the noxious weed species known to occur within the Botany analysis area. Also included in the table are the ratings from the California Department of Food and Agriculture’s noxious weed list (CDFA 2009b) and the California Invasive Plant Council’s invasive plant inventory (Cal-IPC 2006).

Table 78. Noxious Weed Species within the Botany Analysis Area

Species	Common Name	CDFA rating [1]	Cal-IPC rating[2]	Number of sites within:	
				Botany analysis area	Vegetation treatment units
Cardaria draba	hoary cress	B	Moderate	1	0
Centaurea solstitialis	yellow starthistle	C	High	53	40
Cirsium arvense	Canada thistle	B	Moderate	16	10
Cytisus scoparius	Scotch broom	C	High	4	0
Taeniatherum caput-medusae	Medusahead	C	High	44	30

[1] CDFA ratings - *A-listed weeds*: eradication or containment is required at the state or county level; *B-listed weeds*: eradication or containment is at the discretion of the County Agricultural Commissioner; *C-listed weeds*: eradication or containment required only when found in a nursery or at the discretion of the County Agricultural Commissioner.
[2] CalIPC ratings- *High*: attributes conducive to moderate to high rates of dispersal and establishment; usually widely distributed among and within ecosystems. *Moderate*: impacts substantial and apparent, but not severe; attributes conducive to moderate to high rates of dispersal; distribution may range from limited to widespread. *Limited* : ecological impacts are minor or information is insufficient to justify a higher rating, although they may cause significant problems in specific regions or habitats; attributes result in low to moderate rates of invasion; distribution generally limited, but may be locally persistent and problematic.

Cardaria draba (hoary cress)

In California, this deep-rooted perennial occupies disturbed habitats under 4,000 feet in elevation (Chipping and Bossard 2000). It is generally found in moderately moist, alkaline soils; however it can also tolerate a wide range of soil types and moisture regimes (CDFA 2009a).

Once introduced to a site, either through a seed or root fragment, hoary cress can rapidly expand through extension of lateral roots and shoot buds (USDA 2005b). Over the course of one year, a single plant growing in an open site can produce up to 455 shoots that cover an area of 12 feet in diameter (CDFA 2009a). Once established, seedlings quickly develop lateral roots, shoot buds, and tap roots, some of which reach a depth of 25 cm in less than one month. The mature root system of hoary cress can reach depths of three feet or more and can account for 75 percent of the plant’s total biomass (CDFA 2009a). This extensive root system enables plants to survive cold winter climates and periods of drought.

Seeds of hoary cress germinate in the fall after the first rains and are most commonly dispersed by wind, water, vehicles, and agricultural practices. Seeds can remain viable in the soil for up to three years (USDA 2005b).

There is one infestation of hoary cress, which covers approximately 0.2 acres, within the Botany analysis area. This infestation was hand-pulled and mowed on an annual basis between 2002 and 2005. Over this time period, the infestation increased from an estimated 300 plants to approximately 3,000 individuals. Due to the failure of these manual methods to control hoary cress, alternatives A and D propose a combination of mowing and herbicide treatment within this infestation. No treatments for hoary cress are proposed under alternatives B, C, and E due to the lack of feasible and effective non-herbicide alternatives.

Centaurea solstitialis (yellow starthistle)

This highly invasive, deep-rooted winter annual is considered a high priority for control and eradication in Plumas County as well as on the Plumas NF. In California alone, this invasive species is estimated to cover approximately 12 million acres of rangeland and wildland (Duncan and Clark 2005). Dense infestations of yellow starthistle have been shown to reduce the diversity and abundance of native plant species; decrease the value of wildlife habitat and forage; alter fuel characteristics and fire behavior; and deplete soil moisture reserves (Duncan and Clark 2005).

Yellow starthistle reproduces exclusively from seed, with most long-distance dispersal attributed to wildlife or human-related factors (Roche 1992). The control or eradication of this species requires elimination of seed production as well as depletion of the soil seedbank (i.e. seeds residing in the soil that have not germinated). The size of the seedbank is dependent upon the age of the infestation; experimental results suggest that seeds remain viable in the soil for three to ten years (DiTomaso et al. 2006). Yellow starthistle is the most abundant weed in the Botany analysis area (Table 79). It is very common in Indian Valley, which is in close proximity to many of the proposed treatment units. Of the 53 sites within the Botany analysis area, 10 are not proposed for treatment under any of the action alternatives because they are either on private property (1 site); within the boundary of a special use permit (4 sites); or are highly inaccessible (5 sites). Twenty of these yellow starthistle sites have been treated in the past with manual methods as part of the Mt. Hough noxious weed program. Of these, four have decreased and 16 have increased over time; fifteen are currently considered too large to treat with manual methods.

Cirsium arvense (Canada thistle)

This aggressive, perennial thistle is common throughout northern California, where it infests a variety of habitat and soil types (Bayer 2000). It is most competitive in moist, well-aerated, productive soil types, but can also tolerate dry habitats and sandy soil conditions (Bayer 2000). Canada thistle negatively affects native plant species through direct competition for nutrients, light, and water; production of allelopathic chemicals (compounds that inhibit the growth of other plants); and the accumulation of nitrates, which can cause poisoning in animals (Bayer 2000).

Canada thistle spreads either by seed or vegetatively by producing long horizontal underground roots that give rise to aerial shoots (Bossard et al. 2000). Canada thistle's extensive root system has been shown to produce over 66 feet of new roots over a two-year period, some of which have been shown to grow 15 to 20 feet deep. The rates of Canada thistle spread that are documented in the scientific literature range from less than two feet to over 40 feet per year (Donald 1990, Nuzzo 1997, Bond and Turner 2004, USGS 2005)

Canada thistle is a shade-intolerant species, and its growth has been shown to be discouraged in areas where there are low levels of disturbance and sufficient competition from native species. For example, in Rocky Mountain National Park, dry upslope conditions, thick canopies from woody species, and well-established grassy meadows inhibited Canada thistle invasion and population size over time (Beck 1994); however it was also noted that only a minor amount of disturbance (such as from elk grazing) was necessary to promote Canada thistle invasion and establishment.

There are 16 Canada thistle sites within the Botany analysis area. Of these, two are not proposed for treatment because they occur on private property. The remaining 14 sites, which cover an estimated 4.3 acres, are proposed for treatment under alternatives A and D with a combination of aminopyralid and glyphosate applications and prescribed fire. No treatments for Canada thistle are proposed under alternatives B, C, and E.

Cytisus scoparius (Scotch broom)

Since its introduction into California as a landscape ornamental in the mid to late 1800s, this yellow-flowered shrub has aggressively invaded many of the State's disturbed sites and natural areas (CDFA 2009a). Scotch broom is a strong competitor that can quickly form dense thickets, which decrease native plant diversity and have the potential to modify fire frequency and intensity (Bossard et al. 2000). The flowers and seeds of this shrub are also toxic to humans and livestock (CDFA 2009a).

Scotch broom spreads by producing large quantities of seed; one medium-sized plant can produce over 12,000 seeds (Bossard et al. 2000). Seeds are long-lived and can remain viable in the soil for up to 30 years (Bossard et al. 2000). After germination, the initial growth of seedlings can be rapid with some individuals growing over one meter in the first year. Scotch broom is also capable of stump sprouting after cutting, freezing, or fire.

There are four Scotch broom sites within the Botany analysis area. Of these, one occurs on private property and two are included under a previous project; these three sites are not proposed for treatment under the Keddie Ridge Project. The remaining site is proposed for hand-pulling under all of the action alternatives. Although no Scotch broom plants have been seen since the site was discovered and hand-pulled in 2006, follow-up monitoring and treatments are necessary due to the longevity of the soil seed bank.

Taeniatherum caput-medusae (medusahead)

Over the past 20 years, managers of public lands in the western United States have witnessed an explosive spread of this invasive grass species. Medusahead is currently documented in more than 20 counties in California, as well as in Oregon, Washington, Idaho, Nevada, and Utah (Kan and Pollak 2000).

Medusahead is a winter annual grass; its seeds germinate with the first rains of fall, over winter as seedlings, flower in late spring to early summer, and set seed and die by late summer or early fall. This species reproduces by seed, which is primarily dispersed by wind and water, although it can be dispersed to more distant sites by grazing animals, machinery, vehicles, and clothing (Bossard et al. 2000). Medusahead is able to grow in a wide range of climatic conditions and has been documented in plant communities up to 7,000 feet in elevation. On the Plumas NF, most medusahead occurrences are found in relatively disturbed areas along roadsides and railroad tracks; however this grass has also been documented in a few native plant communities.

Medusahead is the second most abundant species in the Botany analysis area (Table 79). It is also common in Indian Valley, which is in close proximity to many of the proposed treatment units. Of the 44 sites within the Botany analysis area, 28 occur within units that will be treated with prescribed fire under all action alternatives. Medusahead is a species of significant concern within the project area because it occurs in sites where there is increased potential for spread (i.e. along roadsides and within units) and available treatment methods are not practical or effective for control.

Environmental Consequences

Effects of the Proposed Weed Treatments on Individual Noxious Weed Species

The following section provides a summary of information for the five noxious weed species that occur within the Botany analysis area; it also provides a discussion of the effectiveness of the different noxious weed treatment measures. The effect to noxious weed species from the five proposed alternatives is presented in a later section. To highlight the differences among the proposed treatments, alternatives that proposed similar noxious weed control measures (i.e. alternatives A and D) were lumped together for the discussion.

Cardaria draba (hoary cress)

Effects from proposed noxious weed treatments

Alternatives A and D

The weed treatments proposed under alternatives A and D will control or eliminate the hoary cress infestation within the Botany analysis area. When used alone, mowing and glyphosate applications provide only variable levels of control; however when they are integrated, these two treatments can be highly effective at reducing hoary cress infestations. Studies of closely related species have shown that mowing followed by glyphosate application can reduce biomass by more than 80 percent after only one year of application (Renz and DiTomaso 2004, 2006). The inclusion of effective weed treatments under alternatives A and D will decrease the risk of hoary cress spread within the Botany analysis area.

Alternatives C and E

Alternatives C and E do not include treatments for hoary cress due to the fact that non-herbicide treatments, such as hand-pulling or prescribed fire, are either impractical or ineffective. Prescribed fire is not an effective control measure because the extensive root system allows hoary cress to survive even a severe fire (Zouhar 2004). Manual treatments, without follow-up herbicide applications, have been unsuccessful at this site in the past. Individuals were hand-pulled and mowed annually over a four year time period, during which the number of plants increased from 300 to 3,000. Manual treatments are also considered infeasible because they require considerable effort. Treatments must occur within 10 days of emergence throughout the growing season, be repeated for two to four years, and be thorough enough to prevent vegetative propagation from small root fragments (USDA 2005b). The lack of effective weed treatments proposed under alternatives C and E will increase the spread of hoary cress within the Botany analysis area.

Centaurea solstitialis (yellow starthistle)

Effects from proposed noxious weed treatments:

Alternatives A and D

The weed treatments proposed under alternatives A and D will significantly reduce large infestations and eradicate small occurrences of yellow starthistle within the Botany analysis area. Under these alternatives, 43 sites (covering approximately 58 acres) are proposed for treatment with a combination of aminopyralid applications, hand pulling, and prescribed fire.

Prescribed burning can be an effective tool for controlling yellow starthistle infestations if timed to occur early in the flowering period, prior to seed production (DiTomaso et al. 1999). Successful control usually requires more than one year of consecutive burning; however some studies have suggested that integrating one year of burning with a follow-up herbicide treatment can be the most effective strategy (DiTomaso and Johnson 2006). Recent studies have shown that aminopyralid provides excellent control of yellow starthistle after one year of treatment, even at low application rates (DiTomaso and Kyser 2006, DiTomaso et al. 2006). Hand pulling, which can be effective for controlling yellow starthistle in small infestations, will be a practical tool for follow-up treatments.

The inclusion of effective weed treatments under alternatives A and D will decrease the risk of yellow starthistle spread within project treatment units and the Botany analysis area.

Alternatives C and E

The weed treatments proposed under alternatives C and E will not eradicate and may not reduce yellow starthistle infestations within the project area. Under these alternatives, only 24 infestations (covering approximately 44 acres) are proposed for treatment with a combination of prescribed fire and hand pulling.

As mentioned above, long-term control of yellow starthistle with prescribed fire alone usually requires more than one year of burning; for example, DiTomaso et al. (1999) determined that three consecutive year of burning were required to reduce the yellow starthistle seedbank by 99 percent. Although a single year of burning can reduce the seedbank by as much as 75 percent, this is not usually sufficient to significantly reduce the infestation (DiTomaso and Johnson 2006).

Hand pulling can be effective for controlling yellow starthistle; however because it is very time-intensive and requires multiple follow-up visits, it is only recommended for small infestations or for those areas of steep terrain where other methods are infeasible. The limited amount of hand-pulling proposed under this alternative will not be sufficient to reduce the extent of yellow starthistle within the project area.

The lack of effective weed control measures will greatly increase the spread of yellow starthistle under alternatives C and E.

Cirsium arvense (Canada thistle)

Effects from proposed noxious weed treatments:

Alternatives A and D

The weed treatments proposed under alternatives A and D will reduce or eradicate Canada thistle infestations within the project area. Under these alternatives, 14 infestations (covering approximately 4.3 acres) are proposed for treatment with a combination of aminopyralid and glyphosate applications and prescribed fire.

Herbicide treatments are the most effective method for Canada thistle control. Aminopyralid has been shown to reduce the density of Canada thistle by over 99 percent in as little as 10 months time, with little impact on the native plant community (Samuel and Lym 2008, Almquist and Lym 2010). Glyphosate is also effective at reducing both shoot and root growth in Canada thistle (Carlson and Donald 1988 *in*

Nuzzo 1997). In their study, Krueger-Mangold et al. (2002) determined that a fall wick application of glyphosate effectively decreased Canada thistle (by an average of 82 percent) while maintaining native species richness.

The effectiveness of prescribed fire treatments at controlling Canada thistle range from positive to negative, and appear to be dependent upon season, soil moisture, and location (Nuzzo 1997). Repeat burning in late spring has shown some reduction in established Canada thistle infestations; however, the overall control is generally considered less than satisfactory and early spring burns have been shown to increase sprouting and reproduction (Zouhar 2001). While fire often kills the above-ground portion of the plant, the roots are often able to survive even high-severity fires and colonize recently burned sites (Zouhar 2001). Prescribed fire alone is not considered to be a viable option for Canada thistle control; however it can be an effective tool when combined with follow-up herbicide applications.

The inclusion of effective weed treatments under alternatives A and D will decrease the risk of Canada thistle spread within project treatment units and the Botany analysis area.

Alternatives C and E

No weed treatments are proposed for Canada thistle under alternatives C and E because non-herbicide treatment alternatives (i.e. manual treatments or prescribed fire) are considered either infeasible or ineffective. Effective long-term control of Canada thistle must focus on killing the roots and root buds, preventing seed production, and preventing re-infestation by seedlings (Zouhar 2001).

Canada thistle is considered particularly difficult to eradicate with mechanical methods due to its ability to spread vegetatively and produce an extensive root system. Repeated hand pulling, which is believed to drain the plant’s reserves because it forces underground roots to produce new shoots (Bond and Turner 2004), has shown variable levels of success for long-term Canada thistle control. On the Plumas NF, one Canada thistle site, selected because of its location within a botanically significant area, has been repeatedly hand pulled since 2003. Over a three-year time period, this site was treated an average of six times during the field season at an average interval of 21 days. To date, treatment of this 2,000-square-foot area has produced little discernable impact on the Canada thistle population.

As mentioned above, Canada thistle’s response to prescribed fire treatment is highly variable and repeated treatments are generally necessary (Nuzzo 1997). Because of the variability of control, prescribed fire treatments alone are not considered a viable option for treatment of Canada thistle infestations.

The lack of effective weed control measures will greatly increase the spread of Canada thistle under alternatives C and E.

Cytisus scoparius (Scotch broom)

Effects from proposed noxious weed treatments:

Alternatives A, C, D, and E

The manual treatments proposed under all of the action alternatives will provide long-term control of the Scotch broom infestation within the analysis area. If manual treatments are feasible, hand pulling can be a highly effective tool for broom removal (CDFA 2009a). On the Plumas NF, eleven Scotch broom sites have been hand pulled annually for an average of five years. Of these, nine have been reduced by an average of 99 percent.

Taeniatherum caput-medusae (medusahead)

Effects from proposed noxious weed treatments:

Alternatives A, C, D, and E

The effectiveness of the prescribed fire treatments at controlling medusahead within the proposed project units is highly dependent upon the timing of the burn. A number of studies have demonstrated that burning medusahead in late spring, prior to seed dispersal can significantly reduce infestations (Rice 2005). In contrast, prescribed burns initiated in the summer and fall, have not been effective due to the fact that the seeds have been dispersed and are on or above the soil where they are protected from the heat of the fire (Kan and Pollak 2000). In many cases, the increased light availability and nutrients as a result of prescribed burning, acts to encourage weed species growth and spread (Hatcher and Melander 2003). From a management perspective, prescribed fire is not always a viable option for medusahead control because the optimal time for controlling infestations is often outside the burn permit parameters (Rice 2005).

Flaming with a propane torch has been tested on medusahead at a limited number of sites on the Plumas NF. Results from these treatments suggest that if flaming is conducted in the spring, over small areas of infestation, it may provide some level of medusahead control (Coppoletta 2006). The major limitation with this method is that it is very time intensive and can only be used on very small, isolated infestations. Flaming may be used in areas that are at a high risk of spread from equipment or personnel.

Other treatments, such as mowing or herbicide application, are not considered practical for medusahead control within the Keddie Ridge Project area. Mowing is nonselective, oftentimes fails to remove the active portion of the plant where new growth originates, and is not recommended along roadsides after seed set because of increased potential for seed dispersal (CDFA 2009a). Glyphosate has shown some level of medusahead control; however its effectiveness has been variable and it is not recommended in native communities where there is a high potential for impact to non-target species.

Based on the variability of the prescribed fire treatments, as well as the low number of sites proposed for treatment (64 percent of the sites in the Botany analysis area), there is a high risk of spread from medusahead under all of the proposed action alternatives.

Effects to Noxious Weeds

The proposed vegetation, fuels, and road treatment activities would greatly increase the risk of noxious weed spread by creating disturbed conditions that favor noxious weed establishment and spread. The implementation of standard management requirements (appendix H) and noxious weed treatment measures would reduce the risk of noxious weed spread; however, this would be highly dependent upon the effectiveness of each proposed control method. For the discussion below, alternatives that resulted in similar effects were grouped together for purpose of the analysis

Alternative B (No Action)

Direct Effects

There would be no direct effects to noxious weed species under this alternative. Of the 118 noxious weed locations that have been documented within the Botany analysis area, 22 have been treated in the past with manual methods. Due to the ineffectiveness of these treatments, only one (Scotch broom) is treated on an on-going basis. Therefore the remaining infestations of hoary cress, yellow starthistle, Canada thistle, and medusahead would continue to spread within the analysis area at their current rates.

Indirect Effects

This alternative would not result in any new ground-disturbing activities so the amount of suitable noxious weed habitat would remain at its current level. Infestations of hoary cress, yellow starthistle, Canada thistle, and medusahead, which are not treated on an on-going basis, would continue to spread at their present rates.

Noxious weed species are oftentimes classified as pioneer species or invaders. Disturbance, whether it is natural (i.e. lightning-caused fire) or associated with management activities, often creates ideal conditions for noxious weed introduction and establishment. Under this alternative, soil disturbance would be minimized and the existing cover of native plant species maintained. These factors could reduce the rate of noxious weed invasion within the analysis area. Some studies have shown that the spread of medusahead may be slowed by competitive perennial vegetation (Davies et al. 2010) while others suggest that Canada thistle invasion can be inhibited by dense canopy cover and well-established competitive meadow species (Beck 1994).

While the no action alternative may decrease the short-term risk of noxious weed invasion by minimizing the amount of disturbance, it will not reduce the long-term risk of disturbance from high-severity wildfire. High-severity wildfires aid in the establishment and spread of noxious weeds by increasing the availability of resources, such as light and nitrogen, and decreasing competition from native plant species. In their comparison of low-severity and high-severity burns, Turner et al. (1997) found that the density of Canada thistle after severe surface and crown fires was two to four times greater than the density after a light surface fire.

Even in the absence of proposed treatments, habitats that are in close proximity to roads, trails, or private land will remain vulnerable to noxious weed invasion and spread. At present, an estimated 37 percent of the noxious weed sites in the Botany analysis area, including three of the largest infestations, occur in close proximity (within 0.1 mile) to the National Forest System land boundary. In addition, approximately 81 noxious weed infestations or almost 70 percent of the known sites, are situated within 100 feet of a road or trail. Roads, whether they are major highways, general forest roads, or motorized vehicle trails, are often the primary conduit for weed introduction and establishment. Roads and motorized trails contribute to dispersal of noxious weed species because they (1) create suitable habitat by altering environmental conditions, (2) make invasion more likely by stressing or removing native species, and (3) allow for easier movement by wild or human vectors (Trombulak and Frissell 2000). Under this alternative, these infestations could act as entry points or seed sources for weeds moving into less-invaded parts of the analysis area.

Cumulative Effects

The effect of specific past management actions on noxious weed species is largely unknown. Targeted noxious weed surveys at the project-level began relatively recently on the forest. Aside from an occasional appearance on a plant list, the first targeted noxious weed survey on file for the Botany analysis area occurred in 2000.

Records for past projects that occurred in the Botany analysis area over the past 20 years were examined to (1) determine if noxious weed species were surveyed for and documented prior to project implementation and (2) if noxious weed species are currently present within the boundary of past projects. Approximately 41 percent of the Botany analysis area weed infestations (48 sites) fall within the boundary of a past project. Of these, only five infestations were documented prior to project implementation. One specific project incorporated standard management requirements, such as equipment cleaning and avoidance measures and conducted manual weed treatments; the infestations within this particular project increased from an estimated 2.4 acres prior to project implementation to approximately 4.4 acres eight years after project completion. While it is often difficult to draw definitive conclusions regarding the effects of past project activities on noxious weeds, the high level of past activity, combined with the current level of weed infestation, suggest that past activities have had a significant effect on noxious weed introduction and spread across the Keddie Ridge Project area.

The lack of ground disturbing activities under the no action alternative would reduce the amount of suitable weed habitat in the short-term; however the lack of weed treatments would allow hoary cress, yellow starthistle, Canada thistle, and medusahead to persist and expand in their current locations and would increase the risk of spread into un-invaded native habitats within the Botany analysis area.

The large number of past activities, the close proximity to private land, and the spatial extent of weed infestations all increase the vulnerability of the landscape to noxious weed invasion, even in the absence of project activities. Vectors for noxious weed spread that are unrelated to the proposed project, such as recreational activities and ongoing forest management (e.g. road maintenance), would continue to aide in the dispersal and spread of noxious weed species in the Botany analysis area.

Alternatives A and D

Direct Effects

The proposed weed treatments, which include manual removal, prescribed burning, and herbicide application, are expected to greatly reduce or eliminate infestations of hoary cress, yellow starthistle, Canada thistle, and Scotch broom within the Botany analysis area. The risk of medusahead spread, which currently lacks a feasible or effective control method, would remain high under all of the action alternatives. The specific treatments, which are proposed for 87 weed sites covering approximately 107 acres, are described in detail in chapter 2. The effectiveness of each method is also discussed in the section above. No direct effects to noxious weed species are anticipated from the proposed vegetation and fuels treatments because infestations will be treated or avoided during project implementation.

Indirect effects

The proposed vegetation, fuels, and road treatments would result in areas with reduced native plant cover and increased soil disturbance; these conditions favor noxious weed establishment and spread. During implementation, project equipment and vehicles could facilitate the spread of noxious weeds by transporting seed and propagative plant parts into un-invaded portions of the project area. In one National Park in Australia, weed seed was found to be most often transported into and around the park by vehicles that had been driven off-road (Lonsdale and Lane 1994).

At the site-specific level, the risk of noxious weed establishment and the potential for spread is largely dependent upon the type and frequency of disturbance associated with each treatment unit. For example, group selection units (i.e., those with relatively high amounts of soil disturbance and vegetation removal) may be at higher risk of invasion than hand thinning units. The amount of soil disturbance associated with the proposed project activities is considered high for alternative A and moderate for alternative D (Table 79).

The five weed species that currently exist within the Botany analysis area can rapidly invade disturbed habitats, particularly in areas where little to no competing vegetation is present. Donald (1990) demonstrated that Canada thistle can spread at a rate of 8 to 12 feet per year in areas with low competition from native plant species. Additionally, some habitats with sparse native vegetation have been shown to be more susceptible to medusahead invasion than more diverse plant communities (Young and Evans 1971). Monitoring of one medusahead site in montane chaparral on the Plumas NF has shown a three-fold increase in infested acres over a period of six years (Coppoletta, personal observation, 2010).

The elevated risk of noxious weed introduction and spread under alternatives A and D would be greatly reduced through implementation of the standard management requirements (refer to appendix H) and the proposed noxious weed treatments. Although these control measures would not remove the risk of noxious weed invasion and spread entirely, they would greatly reduce the potential for noxious weeds to impact native plant communities within the project area. Post-implementation monitoring of past projects with similar vegetation and fuels treatments has shown that aggressive treatment of noxious weeds prior to and through project implementation and incorporation of the standard management requirements have been successful in eradicating small populations of noxious weeds as well as preventing new occurrences (USDA 2006b).

Cumulative Effects

While it is often difficult to draw definitive conclusions regarding the effects of past project activities on noxious weeds, the high level of past activity within the Botany analysis area (discussed under the no action alternative), combined with the current level of weed infestation, suggest that past activities have had a significant effect on noxious weed introduction and spread across the Keddie landscape.

As discussed above, the proposed vegetation, fuels, and road treatment activities would greatly increase the risk of noxious weed establishment and spread in the Botany analysis area by increasing the amount of suitable habitat for weeds. In addition, the close proximity of the project to private land, the existence of on-going activities such as recreation and road maintenance, and the spatial extent of existing weed infestations, all increase the vulnerability of the Keddie Ridge landscape to noxious weed invasion, even in the absence of project activities.

Implementation of the proposed noxious weed treatment measures and standard management requirements, as well as post-project monitoring, would greatly reduce this risk. By directly reducing the density and extent of weeds within the Botany analysis area over time, the cumulative effect of noxious weed spread would be greatly reduced.

Overall, an estimated two percent of the treatment units proposed under alternative A are considered to have a high risk of noxious weed invasion or spread; none of the proposed units under alternative D were classified as high risk. These risk determinations take into account factors such as the amount of soil disturbance associated with the proposed activities; the invasiveness and proximity of the weed to the proposed units; the proportion of infestations proposed for treatment; and the effectiveness of the proposed weed treatment measures. Overall, the risk of noxious weed spread and introduction under alternatives A and D would be (a) slightly greater than the estimated risk under the no action alternative and (b) lower than that predicted under alternatives C and E, where vegetation, fuels, and road treatments are proposed with no effective weed treatment measures in place (Table 79).

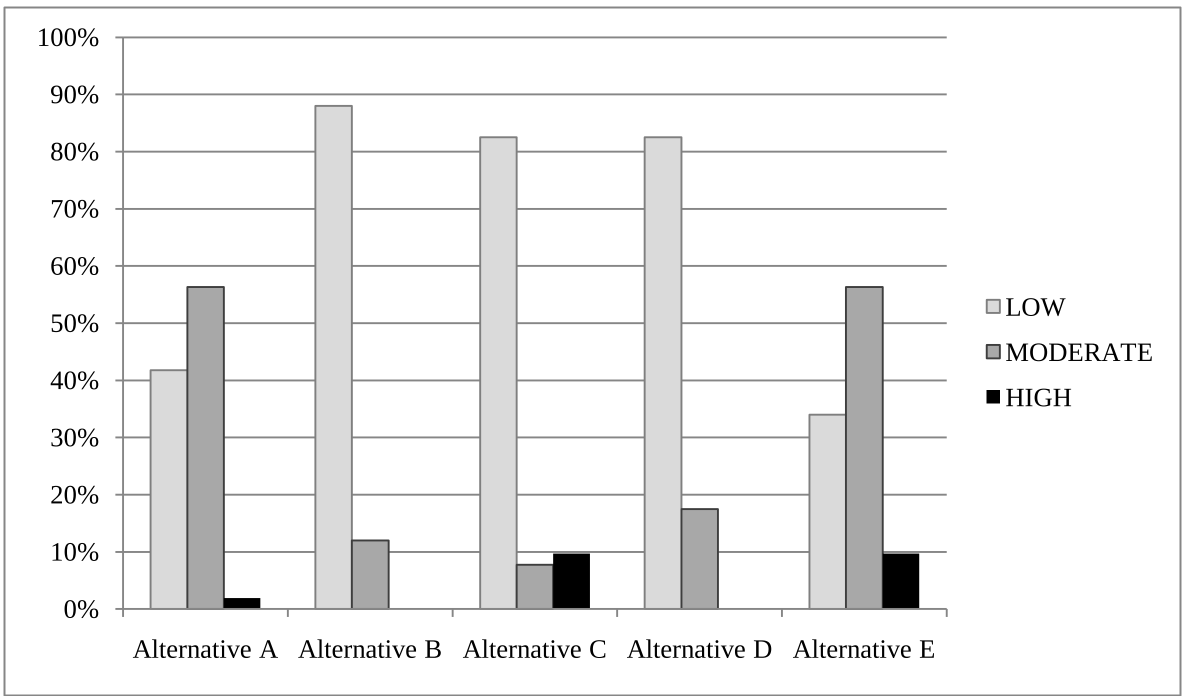

Figure 22. Percentage of Units with Low, Moderate, or High Risk of Noxious Weed Introduction or Spread, Compared Across the Five Alternatives

Alternatives C and E

Direct Effects

The proposed noxious weed treatments, which include manual removal and prescribed burning, would not significantly reduce the existing noxious weed infestations within the Botany analysis area. Less than half (45 percent) of the existing infestations will be treated under these alternatives, primarily due to feasibility constraints and the lack of effective, non-herbicide control methods. Some species that are considered particularly difficult to eradicate with non-herbicide methods, such as hoary cress and Canada thistle, are not proposed for treatment under these action alternatives.

Implementation of standard management requirements (refer to appendix H) would reduce the risk of noxious weed introduction and spread into the project area; however there may be direct effects to noxious weeds from the proposed treatments if they are unable to avoid infested areas during project implementation.

Indirect effects

The vegetation, fuels, and road treatments proposed under these alternatives would result in similar conditions as those described under alternatives A and D. The resulting soil disturbance and removal of native vegetation would increase the probability of noxious weed establishment and spread. In addition, project equipment and vehicles could facilitate weed spread by transporting seed and propagative plant parts to un-invaded portions of the project area (Lonsdale and Lane 1994).

At the site-specific level, the risk of noxious weed establishment and the potential for spread is largely dependent upon the type and frequency of disturbance associated with each treatment unit. For example group selection units (i.e., those with relatively high amounts of soil disturbance and vegetation removal) may be at higher risk of invasion than hand thinning units. The amount of soil disturbance associated with the proposed project activities is considered high for alternative E and moderate for alternative C (Table 79).

The five weed species that currently exist within the Botany analysis area can rapidly invade disturbed habitats, particularly in areas where little to no competing vegetation is present. Donald (1990) demonstrated that Canada thistle can spread at a rate of 8 to 12 feet per year in areas with low competition from native plant species. Additionally, some habitats with sparse native vegetation have been shown to be more susceptible to medusahead invasion than more diverse plant communities (Young and Evans 1971). Monitoring of one medusahead site in montane chaparral on the Plumas NF has shown a three-fold increase in infested acres over a period of six years (Coppoletta, personal observation, 2010).

The elevated risk of noxious weed introduction and spread under alternatives C and E would not be greatly reduced through implementation of the standard management requirements (refer to appendix H) or the proposed noxious weed treatments. Fewer sites (45 percent) are proposed for treatment under these alternatives and the treatments that are proposed are not highly effective. . Infestations of hoary cress, yellow starthistle, Canada thistle, and medusahead, which are not treated on an on-going basis, would continue to spread at their present rates. Infestations that are situated within proposed treatment units will have the highest probability of spread due to these species' ability to rapidly invade disturbed habitats, particularly in areas where little to no competing vegetation is present (i.e. Young and Evans 1971, Donald 1990).

Under alternatives C and E, the proposed treatment activities combined with the limited non-herbicide weed treatments, would be increase the risk of noxious weed invasion and spread and the potential for negative impacts native plant communities.

Cumulative Effects

While it is often difficult to draw definitive conclusions regarding the effects of past project activities on noxious weeds, the high level of past activity within the Botany analysis area (discussed under the No action alternative), combined with the current level of weed infestation, suggest that past activities have had a significant effect on noxious weed introduction and spread across the Keddie landscape.

As discussed above, the proposed vegetation, fuels, and road treatment activities would greatly increase the risk of noxious weed establishment and spread in the Botany analysis area by increasing the amount of suitable habitat for weeds. In addition, the close proximity of the project to private land, the existence of on-going activities such as recreation and road maintenance, and the spatial extent of existing weed infestations, all increase the vulnerability of the Keddie Ridge landscape to noxious weed invasion, even in the absence of project activities.

Implementation of the proposed noxious weed treatment measures and standard management requirements, as well as post-project monitoring, would not be sufficient to reduce this risk. The proposed weed treatments would not reduce the density or extent of weeds within the Botany analysis area over time; therefore the cumulative effect of noxious weed spread would not be reduced.

Under alternatives C and E, approximately ten percent of the proposed vegetation and fuels treatment units are considered to be at high risk of noxious weed invasion or spread (Figure 22). These risk determinations take into account factors such as the amount of soil disturbance associated with the proposed activities; the invasiveness and proximity of the weed to the proposed units; the proportion of infestations proposed for treatment; and the effectiveness of the proposed weed treatment measures. Overall, the risk of noxious weed spread and introduction under alternatives C and E would be (a) greater than the estimated risk under the no action alternative and (b) greater than that predicted under alternatives A and D, where vegetation, fuels, and road treatments are proposed in combination with effective weed treatment measures (Table 79).

Summary of Effects

The proposed vegetation, fuels, and road treatment activities would greatly increase the risk of noxious weed spread by creating disturbed conditions that favor noxious weed establishment and spread. The implementation of standard management requirements (appendix H) and noxious weed treatment measures would reduce the risk of noxious weed spread; however, this would be highly dependent upon the effectiveness of each proposed control method. Table 79 provides a summary of the effects of the proposed alternatives.

Overall, alternatives C and E carry the highest risk of noxious weed introduction and spread, primarily due to implementation of the vegetation, fuels, and road treatments with no effective weed treatment measures in place. Alternatives B (no action) and D have the lowest risk of noxious weed introduction and spread. This is mostly due to the lack of, or reduction in, soil disturbing activities. Alternative A proposes treatments that will likely result in high levels of soil disturbance; however it also proposes to implement highly effective weed treatment measures. In comparison to the other alternatives, alternative A carries a more moderate risk of noxious weed introduction and spread.

Table 79. Summary of Potential Effects on Noxious Weeds.

Indicator Measures	Rankings of Alternatives for Each Indicator[1]				
	Alternative A	Alternative B (No Action)	Alternative C	Alternative D	Alternative E
Amount of soil disturbance associated with the proposed project activities	High	Low	Moderate	Moderate	High
Number of noxious weed infestations proposed for treatment	87	None	53	87	53
Approximate (maximum) number of acres proposed for treatment	107	None	89	107	89
Overall treatment effectiveness	High	None	Variable	High	Variable
Overall Risk Ranking[1]	**3**	**1**	**4**	**2**	**5**

[1] A score of 1 indicates the alternative has the lowest overall risk of noxious weed introduction and spread; a score of 5 indicates that the alternative has the highest overall risk.

Compliance with the Forest Plan and Other Direction

The action alternatives are consistent with the Forest Plan and other direction. A noxious weed risk assessment has been completed for each alternative (FSM 2081.03 and USDA 2004b); the public has been informed of the risk and effects from the proposed project and noxious weeds (USDA 2004b); noxious weed treatment measures have been proposed under some of the alternatives; and control measures (i.e. appendix H) have been identified in areas of high risk (FSM 2081.03).

Economic and Social Environment

Introduction

Analysis Framework: Statute, Regulatory Environment, Forest Plan, and Other Direction

Regulatory Environment

Forest Plan

The guidance for economic and social environment is provided in the 1988 Plumas National Forest Land and Resource Management Plan, as amended by the 1999 Record of Decision on the final environmental impact statement for the Herger-Feinstein Quincy Library Group Forest Recovery Act, the 2004 Record of Decision on the final environmental impact statement EIS for the Sierra Nevada Forest Plan Amendment.

Effects Analysis Methodology

Specific Assumptions

This economic analysis focuses on those revenues and treatment costs associated with implementing fuel reduction treatments and forest health activities, in the Keddie Ridge Project area. The purpose of this economic analysis is to present the potential revenues and costs associated with each of the alternatives for comparison purposes.

This analysis does not include monetary values assigned to resource outputs such as wildlife, watersheds, soils, recreation, visual quality, or fisheries. It is intended only as a relative measure of differences between alternatives based on direct costs and values used.

Employment opportunities can have direct, indirect, or induced effects on the local economy. Direct effects are associated with the primary producer. For example, the manufacturing of lumber from the Keddie Ridge Project area would have a direct effect on employment opportunities. Indirect effects account for employment in service industries that serve the lumber manufacturer. These industries may include logging, trucking, and fuel suppliers. Induced effects are driven by wages, and are circulated through the local economy for food, housing, transportation, and other living expenses. The sum of direct, indirect, and induced effects is the total economic impact in terms of jobs and monetary outputs. It was assumed for this analysis that 10 to 15 jobs are created per million board feet of timber harvested. This number includes direct, indirect and induced jobs. It was assumed for this analysis that most products from the Keddie Ridge Project area would be processed locally due to high hauling costs of products. Likewise, it is also assumed that most employment would largely be derived from Plumas County for the timber harvesting activities.

Specific Methodology

Timber harvest values used in this economic analysis were based on the pond values (delivered log prices) of local mills from the State Board of Equalization. Harvest costs and road improvement costs were developed from the latest timber sale appraisal values. Reforestation treatments are based on the latest service contract prices and Knutson-Vandenberg sale area improvement plans. The “IMPLAN” software program was utilized in the input/output analysis for monetary outputs to the local economy.

Data Sources

The social and economic figures were obtained from State and Federal maintained databases. The most current reports were run as well as several years earlier in order to correlate with current year’s information. Statistics were obtained from the U.S. Census Bureau, America Community Survey, Censtats, Business and Industry, Bureau of Labor Statistics, Bureau of Economics, and California Department of Finance.

Affected Environment

The Plumas National Forest contributes to the regional economy in two primary ways: (1) through the generation of income and employment opportunities for residents of the immediate area, and (2) through direct and indirect contributions to local county revenues. The Plumas National Forest also contributes in secondary ways, such as through production of goods and services in local and regional markets.

Although some economic effects are dispersed over a broad area, the most substantial impacts are felt locally in Butte, Plumas, Lassen, Sierra, and Yuba Counties. Table 80 shows the percentage of Plumas National Forest land in local counties. The National Forest System lands account for approximately 72 percent of Plumas County. Consequently, management of National Forest System lands has a notable effect on the regional economy of Plumas County.

Table 80. Percentage of National Forest System Lands by County (Based on GIS Data)

County	County Acres	Beckwourth Ranger District (acres)	Feather River Ranger District (acres)	Mount Hough Ranger District (acres)	Total National Forest System Lands in Each County (acres)	National Forest System Lands within Each County (percent)
Butte	1,072,708	0	143,517	0	143,517	13.4
Lassen	3,022,136	39,686	0	1,635	41,320	1.4
Plumas	1,672,778	448,365	183,210	579,196	1,210,771	72.4
Sierra	615,514	14,794	33,522	0	48,316	7.8
Yuba	411,695	0	33,734	0	33,734	8.2
Totals	**6,794,830**	**502,844**	**393,984**	**580,831**	**1,477,659**	**21.7**

Industry/Employment

The two employment sectors most related to forest planning processes are the timber industry and tourism. Forest planning processes can positively affect the farm industry (logging operations), manufacturing (mills), transportation (trucks and railroad) and utilities (biomass power plants). They are very difficult to quantify, in terms of both total employment and their relative importance to local economies, because state and federal statistical gathering agencies generally do not break down employment data specific to logging and lumber; rather it is lumped under farm manufacturing and transportation industries. industries.

The timber industry resides within two industries, (1) Farm and (2) Manufacturing. According to the Bureau of Economic, Farm and Manufacturing earnings in Plumas County represent 11.73 percent of the major industries in Plumas County. Earnings in these two industries have decreased and are experiencing negative growth. Employment in farm and manufacturing represents 7.87 percent of the jobs in Plumas County. The per capita personal income in 2008 was $38,525. The total personal income for Plumas County was $784 million. Output for all industries in Plumas County is $1.1 billion. There are six employers in logging operations, and seven employers related to forestry services totaling 104 jobs. There are two large mills in the local area within distance of the project area combined employment is under 500 employees. The value of the mills total production is at $91 million.

Plumas County labor statistics reflect a seasonal labor force with employment up during the warmer months. In the winter unemployment rises as the timber harvesting season stops, contributing to the unemployment rate as reflected in Table 81 and Table 82. The housing downturn has had an impact on the unemployment rates in Plumas County; nearly doubling the unemployment rate during the months when normal employment rates go up. In 2009 between May and September the unemployment rates nearly doubled as reflected in the information obtained from the Bureau of Labor Statistics. This project can have a significant effect on the numerous industries' employment in the local labor force and transient labor force.

Table 81. Bureau of Labor Statistics, Plumas County Unemployment Rate

Year	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

Energy

Plumas County has two co-generation plants and two biomass power plants operating within a reasonable haul distance. The Wendell facility is 35 megawatt plant and when operating at full capacity uses 550 bone dry tons/ day or 37 truck loads. The Wendell facility sells to PG&E approximately 30 megawatts a day when they can produce at full capacity. Presently they cannot produce full capacity due to the lack of biomass material. The Westwood facility is a 10 megawatt plant that employs 10 to 19 people. The Westwood facility when operating at full capacity uses 200bone dry tons/day.

County, State and Federal Taxes

Forest contributions to local county revenues come from three sources: (1) Payments in Lieu of Taxes, a standard rate, (2) (2) *Receipt Act* payments or payments from the *Secure Rural Schools and Community Self-Determination Act of 2008* ,a fixed rate, (3) timber yield taxes that fluctuate based on timber sold.

Payments in Lieu of Taxes

The Bureau of Land Management administers the Payments in Lieu of Taxes, which apply to many different types of federally owned land, including National Forest System lands. Payments in Lieu of Taxes compensate counties for the loss of property tax revenues due to nontaxable federal land in the county.

Secure Rural Schools and Community Self-Determination Act

The *Secure Rural Schools and Community Self-Determination Act* 2008, offers counties an alternative to the *Receipt Act*. A county may choose to continue to receive payments under the *Receipt Act* or to receive its share of the state's full payment amount under the *Secure Rural Schools and Community Self-Determination Act*. Table 83 reflects Plumas County's payments of $7,000,000 for the past several years.

The *Secure Rural Schools and Community Self-Determination Act* payments are set to expire September 2011. This Act provides payments to counties regardless of the amount of timber harvested. The payment is based on a complicated formula that takes into account in part acres of National Forest System lands, population and per capita income. When or if this Act terminate then counties will continue to receive payments under the Receipt Act at 25% of the harvested value from the National Forest System lands contained within the county. Table 83 list payments made to counties partially based on acres of National Forest System lands within the county boundary. If Plumas County reverts back to the Receipt Act collections then each project and the timber harvested become significantly important to Plumas County and its residence, as education and road safety will be impacted with each commercial project the Plumas National Forest implements.

Table 83. *Secure Rural Schools and Community Self-Determination Act* Full Payment Amounts to Counties for Fiscal Years 2001-2007

	Butte	Lassen	Plumas	Sierra	Yuba
2001	$866,419	$3,751,241	$7,024,648	$1,788,350	$231,268,
2002	$873,350	$3,781,250	$7,080,847	$1,802,657	$233,118
2003	$883,830	$3,826,626	$7,165,816	$1,824,289	$235,915
2004	$895,320	$3,876,372	$7,258,972	$1,848,005	$238,982
2005	$915,912	$3,965,528	$7,425,928	$1,890,509	$244,479
2006	$925,071	$4,005,183	$7,500,187	$1,909,414	$246,924
2007	$923,173	$3,996,963	$7,484,795	$1,905,495	$246,417
2008	$832,565	$3,604,665	$6,750,168	$1,718,472	$222,231
2009	$749,308	$3,244,198	$6,075,151	$1,546,625	$200,008
2010	$675,302	$2,923,783	$5,475,136	$1,393,872	$180,254
Total	$8,540,250	$36,975,809	$69,241,648	$17,627,688	$2,048,328

Timber Yield Taxes

The third source of revenues to local government is the timber yield tax, which is administered by the State Board of Equalization. The Forest does not pay this tax; instead, it is paid by private timber operators, based on the amount of timber harvested in a given year on both private and NFS lands. The tax is 2.9 percent of the value of the harvested timber. The taxes are collected by the state, and approximately 80 percent is returned to the counties from which the timber was harvested. The amount of revenues disbursed to the counties can be affected by decisions about the amount of timber to be offered for sale each year on the Forest. The volumes harvested from Plumas County indicate a downward trend with a notable positive shift of volume harvested from NFS lands in 2009, due to the salvage of timber from numerous fires. In Table 84 a downward trend of volume harvested on NFS lands has occurred since 1994 as reported by the Board of Equalizations tax records.

Table 84. Plumas County Percent of Volume from National Forest System Lands

Year	Percent
1994	37%
2005	15%
2006	22%

2007	11%
2008	10%
2009	29%

Source: California Board of Equalization

Plumas County in 2005 produced 107,817 mmbf of timber which is 6 percent of the volume produced in the State of California as documented in the California Department of Finance. According to the California Board of Equalization 15 percent of the volume from Plumas County came from NFS lands including the Forest Service; a total of 16 mmbf.

Timber Harvest Trends

The harvest of trees provides commercial and noncommercial wood products, such as sawlogs and biomass, to the local economy. Local sawmills that rely, at least in part, on logs from National Forest System lands include Sierra Pacific Industries in Quincy and Collins Pine Company in Chester. Figure 23 displays the volume of timber harvested on the PNF since 1978. Local sawmills have processed most of this volume although mills as far away as Weaverville and Roseburg have bid or purchased timber from the Forest.

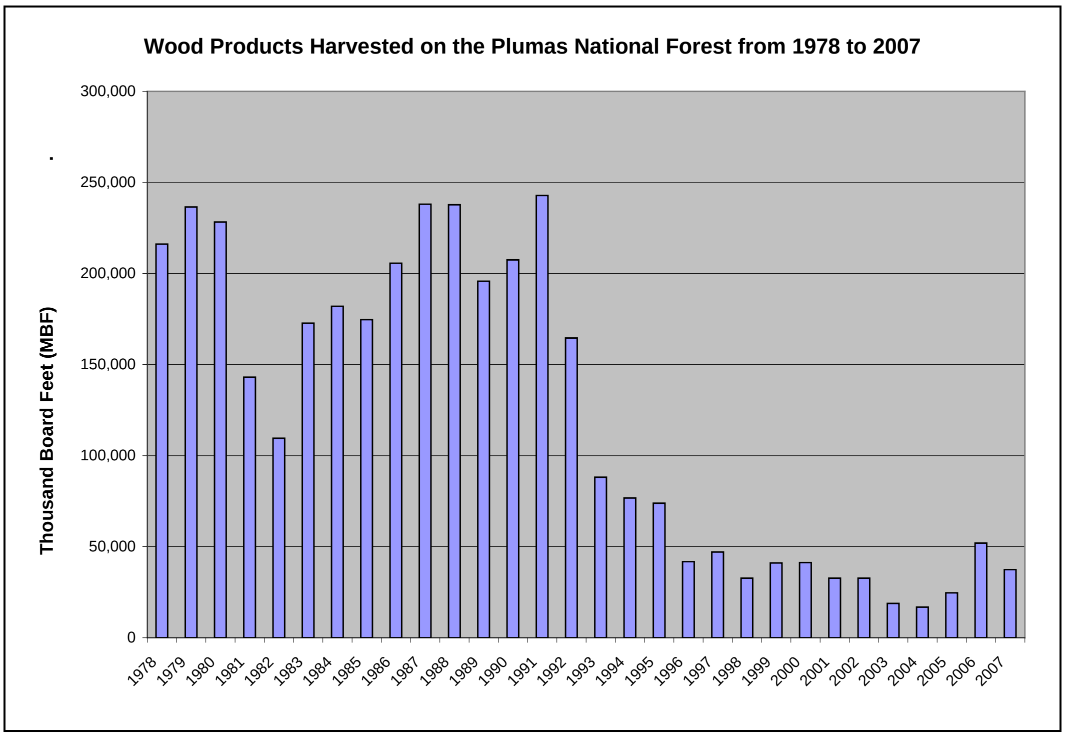

Figure 23 Annual Amount of Wood Products Sold on the Plumas National Forest from 1978 to 2007

Environmental Consequences

Alternative A – Proposed Action

Direct and Indirect Effects of DFPZ and WUI Fuels Reduction Treatments

Economic effects are determined by the value of products and services for each alternative (which includes the no action alternative) considered in this analysis. The level and mix of goods and services available to the public varies by alternative. The effects discussed in this section include estimated government expenditures for cost of services and revenues from the value of timber and biomass, as well as monetary impacts on local communities.

Direct monetary effects are discussed in terms of net cash value to the U.S. Treasury, including the costs associated with implementing the treatments; and direct, indirect, and induced job opportunities. In general, the monetary value of each alternative depends on the amount and method of timber harvest, type of treatment and the acreage planned for treatments.

The anticipated timber volume, value, costs, service treatment costs, and jobs, are displayed for all alternatives in Table 85. The revenue generated would also depend on the availability of logging equipment, haul distances to available mills, and fuel prices. This analysis assumes equipment cost and not full ownership of equipment, and hauling to the closest mill. However, haul to other mills is feasible as evidenced by past and current timber sales. Table 85, summarizes the economic effects to the local economy that would occur from implementation of alternative A, C, D, and E.

Table 85. Comparison of Economic Effects by Action Alternative

Revenue/Cost Employment	Alternatives			
	Alternative A	Alternative C	Alternative D	Alternative E
Sawlog Volume	10.37 mmbf	231 mbf	1.9 mmbf	15.48 mmbf
Biomass Volume	21,000 gt	24, 000 gt	13,000 gt	18,000 gt
Sawlog and Biomass Value (cost deducted)	$2,127,902	$556,180	$580,450	$3.001,415
Additional Operation Cost	$2,186,298	$1,442,220	$1,184,091	$2,453,130
Potential Advertised Value to the Government	$130,301	$2,772	$22,800	$202,488
Percent Above Value	-3%	-160%	-104%	18%
Fuels Reduction Project Costs	$5,496,675	$5,496,675	$5,334,351	$5,496,675
Potential Direct and Indirect Jobs	189	60	66	252
Potential Employee Income	$6,799,620	$2,161,134	$2,374,303	$9,082,986
Receipt Act Plumas County Estimate Collections	$32,575	$693	$5,700	$50,622

All action alternatives would create additional employment opportunities in service industries (such as logging supply companies, trucking companies, and fuel suppliers) that serve the timber industry. The local economy, driven by wages would improve stability for the small communities throughout the county. Wages paid to workers would circulate through the local economy for food, housing, transportation, and other living expenses.Harvesting and forest health improvement treatments would generate 189 direct and indirect jobs with alternative A. Some of the other industries to benefit from activities associated with alternative A are retail, newspaper, data processing, banks, real estate, waste management, college, doctors, hospitals, child care services, lodging, electric power, and gas distribution.

This project would generate $1,595,051[1] in Federal Tax collections and $730,189[2] in state and local tax. The Keddie Ridge Project area would create an induced income of $2,537,185 throughout numerous business sectors and generate induced outputs of 18 percent of the total project inputs for other businesses in the community.Potential electricity produced from the biomass is 550 MWH with a potential retail value of $75,900. Table 86 displays the value generated by this alternative by industry, as well as the indirect effects and the induced effects on the local economy.

[1] “”Values generated through IMPLAN software an Economic Modeling Program

[2] “”

Table 86. Alternative A Output Impacts on Expenditures by Industry in Plumas County

Industry	Direct Effects[4]	Indirect Effects[5]	Induced Effects[6]
Commercial Logging	$3,918,422	$959,888	$784
Support activities for forestry	$5,498,075	$45,431	$499
Sawmill	$3,860,026	$285,285	$4,780
Transportation	$1,177,803	$57,855	$12,703
Other Business Sectors		$697,683	$2,522,419
Total value to Plumas County Economy	$14,454,326	$2,046,142	$2,537,185

Values generated through IMPLAN software, an Economic Modeling Program
[4]Direct Effects represents the impacts for the expenditures and/or production values specified as direct final demand changes.
[5]Indirect Effects represents the impacts caused by the iteration of industries purchasing from industries resulting from direct final demand changes.
[6]Induced Effects represents the impacts on all local industries used by the expenditures of new household income generated by the direct and indirect effects of direct final demand changes.

This alternative would have a positive effect on the overall economic activity in Plumas County. This project would help provide stability and revenue to the manufacturing industry, farming industry (logging operators), transportation (haul trucks and equipment), and indirect industries (housing, food, education, etc.). Alternative A would help sustain employment for families and generate harvest revenues for local businesses and provide the state and county timber yield taxes. These collections would help the county provide services such as road maintenance and education. The saw-timber provided by the action alternatives contributes to the stability of local economy by providing a supply of wood products to local industries dependent on forest management activities. Refer to appendix D of this EIS for the complete economic analysis by alternative.

Alternative B – No Action

Under alternative B, no treatments would be implemented. There would be no implementation costs. Under the no action alternative, no funds would be generated for the U.S. Treasury or returned to local counties through the receipt tax. No additional employment opportunities or wages paid to primary and service industry employees would circulate through the local economy.

The no action alternative would result in a negative effect on the local industries that depend on service contracts or a steady supply of timber, as well as counties that use timber yield taxes to fund county programs. Local industries would have notably reduced opportunities related to forest management activities such as timber harvesting and forest health projects. Additionally, the local economy would not receive benefits from associated employment, such as in food, lodging, and transportation businesses. The unemployment rate could potentially stay constant throughout the year, at double the national unemployment rate. The income loss for families would trickle throughout the local economy affecting many of the local industries in a negative way.

The economic resiliency of Plumas County is low. The major industries manufacturing lumber, the logging operators, transportation, the Forest Service and the county are all inter-connected and represent nearly 40 percent of employment. If manufacturing of lumber is diminished or stopped, then all of these industries would be affected by the lack of production by the mill. There is not another industry which can carry the community through economic lows.

Throughout northern California, cumulative years of reduced timber harvesting activities (including those on federal lands) have resulted in the loss of infrastructure to complete such activities. The loss of such infrastructure, including local mill closures and corresponding loss of logging companies could significantly reduce or eliminate future economic and environmental opportunities from National Forest System lands. The Plumas National Forest is unique in that the infrastructure is still in place; however these industries in the county are experiencing numerous years of negative growth and may be faced with lay-offs, mill closures, and operators liquidating equipment. The loss of this industry will have a negative effect on managing NFS lands in a cost effective manner. The continuation of current conditions under alternative B would preclude and/or notably limit opportunities for long-term employment and rural community stability.

Alternative C – Non-Commercial Funding Alternative

The sole purpose of alternative C is to reduce hazardous fuels. The jobs generated would be from service contract providers with some harvesting jobs. This alternative would generate 60 direct and indirect jobs. Alternative C would have the least employment potential in comparison to the other action alternatives. This alternative is in strong support of forestry labor intensive opportunities in service industries (such as logging supply companies, and fuel suppliers) that serve the support forestry activities. Wages paid to workers would circulate through the local economy for food, housing, transportation, and other living expenses. This project would generate $1,259,732[3] in federal tax collections and $530,643[4] in state and local tax. The Keddie Ridge Project area would create induced income of $581,108 for other business sectors in Plumas County. This project would generate induced outputs for the business sectors of 26 percent of the total project inputs. Table 87 displays the value generated by this alternative by industry and the indirect effects and the induced effects on the local economy. Potential electricity produced from the removed biomass is 600 MWH with a retail value of $82,800. Some of the other business sectors to benefit from activities associated with alternative C are similar to alternative A, housing, food, and education.

3 “”

4 “”

Table 87. Alternative C Output Impacts on Expenditures by Industry in Plumas County

Industry	Direct Effects[4]	Indirect Effects[5]	Induced Effects[6]
Commercial Logging	$960,270	$199,996	$628
Support activities for forestry	$5,496,675	$10,988	$400
Sawmill	$745,239	$55,821	$3,825
Transportation	$499,290	$16,376	$10,165
Other Business Sectors		$228,062	$2,015,277
Total value to Plumas County Economy	$7,701,474	$511,243	$2,030,295

Values generated through IMPLAN software an Economic Modeling Program
[4]Direct Effects represents the impacts for the expenditures and/or production values specified as direct final demand changes.
[5]Indirect Effects represents the impacts caused by the iteration of industries purchasing from industries resulting from direct final demand changes.
[6]Induced Effects represents the impacts on all local industries caused by the expenditures of new household income generated by the direct and indirect effects of direct final demand changes.

Alternative D – 2001 SNFPA ROD Consistent

Alternative D is predominantly forest health and hazardous fuels reduction treatments with timber product removal. The jobs generated would be from service contract providers with some harvesting jobs. This alternative would generate 66 direct and indirect jobs. Alternative D would have slightly larger job creation in comparison to alternative C. This alternative is in strong support of forestry labor intensive opportunities in service industries (such as logging supply companies, and fuel suppliers) that serve the support forestry activities. Wages paid to workers would circulate through the local economy for food, housing, transportation, and other living expenses. This project would generate $1,193,944[5] in federal tax collections and $498,524[6] in state and local tax. The Keddie Ridge Project area would create induced income of $554,297 for other business sectors in Plumas County. This project would generate induced outputs for other business sectors of 27 percent of the total project inputs. Table 88 displays the value generated by this alternative by industry and the indirect effects and the induced effects on the local economy. Energy that may be produced from the removed biomass is approximately 325 MWH of electricity with a retail value of $44,850. Some of the other business sectors to benefit from activities associated with alternative D are similar to alternative A include food, housing and education.

5 “”
6 “”

Table 88. Alternative D Output Impacts on Expenditures by Industry in Plumas County

Industry	Direct Effects[4]	Indirect Effects[5]	Induced Effects[6]
Commercial Logging	$783,903	$158,357	$599
Support activities for forestry	$5,334,351	$8,961	$381

Transportation	$383,308	$12,957	$9,696
Other Business Sectors		$187,543	$1,922,299
Total value to Plumas County Economy	$7,082,012	$411,389	$1,936,624

Values generated through IMPLAN software, an Economic Modeling Program
[4]Direct Effects represents the impacts for the expenditures and/or production values specified as direct final demand changes.
[5]Indirect Effects represents the impacts caused by the iteration of industries purchasing from industries resulting from direct final demand changes.
[6]Induced Effects represents the impacts on all local industries caused by the expenditures of new household income generated by the direct and indirect effects of direct final demand changes.

Alternative E – 2004 SNFPA ROD Consistent

This alternative has a mix of harvesting and forest health improvement treatments. The jobs generated would be from service contract providers, the logging sector and manufacturing sector. This alternative would generate 252 direct and indirect jobs. This alternative is similar to alternative A in support of forestry labor intensive opportunities and the manufacturing of lumber. Wages paid to workers would circulate through the local economy for food, housing, transportation, and other living expenses. This project would generate $1,561,911[7] in federal tax collections and $698,403[8] in state and local tax. The Keddie Ridge Project area would create induced income of $683,886 for other business sectors in Plumas County. This project would generate induced outputs for other business sectors of 20 percent of the total project inputs. Table 89 displays the value generated by this alternative by industry and the indirect effects and the induced effects on the local economy. Energy that may be produced from the removed biomass is approximately 450 MWH of electricity with a retail value of $62,100. Some of the other business sectors to benefit from activities associated with alternative E are similar to alternative A, are food, education, and housing.

Heritage Resources

History of the Project Area

General Prehistoric Overview for the Plumas National Forest

The following is a broad historical overview of the human or heritage mechanisms that have influenced the Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project). Ecosystem models based solely on biological and physical elements often disregard the complex interaction between humans and their environment. More than any other phenomenon, heritage landscapes provide a unique opportunity to interpret the history of the effects humans have had on the environment. Together, natural and heritage influences have shaped the overall character of the project vicinity. Prehistory Period is defined as generally from 8,000 years ago to the 130s. Historic Period is defined as generally between the 1930s to 50 years ago.

Prehistory Period

Archaeological studies on the Mt. Hough Ranger District have primarily been limited to heritage resource inventories for proposed Forest Service activities. Intensive archaeological research in the Keddie Ridge Project area, allowing for a refined definition of prehistoric complexes and establishment of a reliable heritage chronology,is sparse. Therefore, heritage assessments and interpretations for the Keddie Ridge Project area rely upon extrapolations from several studies that were completed for lands adjacent to the Keddie Ridge Project area.

Archeological investigations on the Plumas National Forest have revealed Native American occupation spanning at least 8,000 years. Heritage resources include flaked-stone artifact scatters, which reflect resource procurement activities and seasonal campsites, habitation sites with cultural deposits, and in some instances, house pits.

Only a few projectile points have been identified within Plumas County that date to the Paleo-Indian period between 9000–6000 B.C. (Nilsson et al. 1996). Later assemblages are summarized under two comprehensive archaeological periods, the Archaic Period and Emergent Period. These two periods date between 6000 B.C.–A.D. 500 and A.D. 500–Historic Contact, respectively. The Archaic is also generally divided into Lower (6000–3000 B.C.), Middle (3000–1000 B.C.), and Upper (1000 B.C.–A.D. 500).

Prehistoric material culture in the northern Sierra region of California has been further categorized according to local chronologies that define technological, economic, social and ideological elements. This northern Sierra region includes the drainages of the upper Feather, Yuba, Bear, and American Rivers and Lake Tahoe. The Martis-Kings Beach chronological sequence was first developed by Heizer and Elsasser (1953) after an extensive survey of the area around Lake Tahoe. The sequence was revised later by Elsasser (1960), Elston (1971), Elston et al. (1977), Humpreys (1969), Ritter (1970), and Elsasser and Gortner (1991).

The Tahoe Reach chronological sequence by Elston et al. (1977) has been adopted and used by the majority of archaeologists working in the north-central Sierra mountains and foothills, though questions have been raised about its validity (for example refer to Jackson et al. 1994). Some of these issues were examined recently by Basgall (2003). A second chronological scheme (Mesilla-Bidwell-Sweetwater-

Oroville-Historic) was developed for the west slope of the Sierra foothills, summarized by Ritter (1970) based on work at Lake Oroville, and later by Kowta (1988) based on his work at Lake Almanor. Prehistoric influences from both the high Sierra and Great Basin to the east (Martis Complex) and from the Sacramento Valley to the west have been recognized within this western foothill sequence. Recently, for example, as a result of shoreline surveys at Lake Almanor, Compas (2003) identified Martis, Mesilla, Sweetwater, and Kings Beach assemblages, among others.

Although assemblages earlier than the Martis Complex (Spooner and Tahoe Reach phases) have been tentatively identified as part of the Tahoe Reach sequence (Elston et al. 1977), the Martis Complex is the earliest well-documented phase. The sequence attempted to show continuity in development of culture, using projectile point typologies, from the Martis and Kings Beach complexes through ethnographic times. Using this argument, the Kings Beach is taken to represent the Washoe, with ancestral Washoe represented by the Martis Complex (Elston et al. 1977; Kowta 1984). This assessment, however, is not universal (Moratto 1984). Elston and others also suggest that prehistoric occupation of the Sierras may have occurred as a result of the movement westward of peoples from the Great Basin. Kowta (1988) suggested Penutian-speaking peoples from the east displaced indigenous Sierran Hokan speakers about A.D. 1000.

The seven phases of the Tahoe Reach sequence (Elston et al. 1977), which spans most of the Holocene, are summarized in Table 90. The Martis and Kings Beach complexes account for five of the seven phases; these two complexes are detailed below.

Martis Complex (2000 B.C. – A.D. 500)

This well-documented complex has been identified from the Lake Tahoe area, extending northward into Plumas and Lassen Counties, as well as southward into Alpine County (Elsasser 1960). Radiocarbon dates and obsidian hydration measurements indicate the complex was present from 2000 B.C. to A.D. 500 (Elsasser and Gortner 1991). Excavation of Martis Complex sites included the Chilcoot Rockshelter in Plumas County (CA-PLU-44; Payen and Boyolan 1961). Characteristics of the Martis Complex include an emphasis on hunting and seed collecting. Projectile points were large, heavy, and roughly flaked; they also varied in form (although they resemble Great Basin forms, including the Elko series). An abundance of distinctive tool forms included finger-held drills or punches, large biface blades and cores, spokeshave-notched tools with a concave edge, and basalt pressure-retouched flake “scrapers.” For the manufacture of flaked tools, there was an apparent preference for using local basalt other than chert or obsidian. The milling equipment used to process seeds was predominantly grinding slabs and handstones.

Table 90. Cultural Phases of the Tahoe Reach Chronology

Age	Phase	Characteristics	Climate
A.D. 1200–Historic Contact	Washo-Late Kings Beach	Desert Side-notched and Cottonwood Series points, chert cores, utilized flakes, and other small chert tools.	Neoglacial; wet and cool but with little summer precipitation
A.D. 1200–500	Early Kings Beach	Eastgate and Rose Spring series points, chert cores, utilized flakes, and other small chert tools.	Nonglacial; dry, trees growing in former bogs; Tahoe does not overflow often
A.D. 500–500 B.C.	Late Martis	Corner-notched and eared points of the Martis and Elko series Large side-notched points Large basalt bifaces and other basalt tools.	Neoglacial; wet but not necessarily cooler, increased summer precipitation
500 B.C?–1500 B.C.	Middle Martis	Steamboat points, other types in Elko-Martis series Large basalt bifaces and other basalt tools.	Possible warm, dry interval centered on 1500 B.C.
1500–2000 B.C.	Early Martis	Contracting stem points of the Elko-Martis series Large basalt bifaces and other tools. Light-colored basalt artifacts	Beginning of Meditherimal; Neoglacial, wet but not necessarily cooler, increased summer precipitation; Tahoe begins to overflow
2000–5000 B.C.	Spooner	Point in the Pinto and Humboldt series, light-colored basalt artifacts.	Altithermal; generally hot and dry; Tahoe does not overflow for long periods of time
6000 B.C.	Tahoe Reach	Parman points.	Anathermal; warming trend, climate similar to later Neoglacial intervals

The most important mountain valleys inhabited by the Maidu included American, Big Meadows (now under Lake Almanor), Butt, Genesee, Indian, Mountain Meadows, and Red Clover (Riddell 1978). One or more permanent villages were established in these valleys, winter weather permitting. Occupation was restricted to seasonal use in other valleys, including Sierra and Mohawk. The nearest recorded Maidu villages to the Keddie Ridge Project area would have been Tse'lim-nah and Yow'-koo, located in the North Arm of Indian Valley.

Political organization of the Maidu was limited to a settlement pattern of village communities (Kroeber 1925; Riddell 1978). A central village housed a circular, semi-subterranean ceremonial assembly structure and the home of the community spokesman. A community was composed of 3–5 villages, and the villages were apparently self-sufficient. Kroeber (1925) estimated village size as less than 200. Houses were either semi-subterranean or conical bark structures. Because of water discharge during the spring and summer snowmelt, villages were situated on the edges rather than the center of the valleys. Each village community owned and defended their common hunting and fishing grounds near these mountain valley settlements. Some fishing holes and deer fences were owned by individual families and inherited by male descendants.

The fundamental economy of the Maidu was one of subsistence hunting, fishing, and collecting plant foods in an area where abundant natural resources varied seasonally (Riddell 1978). Acorns were a dietary staple, and were collected from oak groves at lower elevations. Oak varieties in the area included the black oak (*Quercus kelloggii*), canyon or golden oak (*Q. chrysolepis*), and interior live oak (*Q. wislizenii*). The Maidu gathered nuts from the sugar pine and yellow pine and ate them raw or cooked into a soup or patties. In the northeastern part of their territory near Susanville, nuts from the huckleberry oak (*Q. vaccinifolia*) and bush chinquapin (*Chrysolepis sempervirens*) were also collected. Other vegetal resources included (*Corylus cornuta var. californica),* hazelnuts, buckeye nuts, wild nutmeg, grass seeds, berries, and underground roots and bulbs. Roots included camas, Indian root, cattail root, and tule root. Camas roots were harvested early in the summer and roasted in rock-lined cooking basins (Waechter 2005). Salmon, eel, birds, waterfowl, grasshoppers and other insects, as well as large and small mammals, were also consumed. Large animals included deer, elk, and grizzly bears.

A wide variety of tools, implements, and enclosures were employed by the Maidu to gather and collect food resources. These included the bow and arrow, traps, nets, slings, snares, clubs, and blinds for hunting land mammals and birds; salmon gigs, traps, and nets for fish. During communal drives, deer were driven over cliffs or shot by concealed hunters. Woven tools, including seed beaters, burden baskets, and carrying nets, as well as sharpened digging sticks, were used to collect plant resources. Snowshoes were used for winter travel, and dugout canoes or log rafts for navigating or crossing the mountain waterways (Riddell 1978).

The Maidu processed food resources with a variety of tools, including portable stone mortars, bedrock mortars and pestles, anvils, woven strainers and winnowers, leaching baskets and bowls, storage baskets, woven parching trays, wooden mortars, and knives. Baskets were either coiled or twined. They also traded between neighboring Konkow for various resources and implements, and with the Achumawi for beads, obsidian, money beads, and green pigment dye.

Log drums, rattles, flutes and whistles accompanied Maidu ceremonial dances. Mortuary practices among the Maidu included extended burials, generally facing east, that were accompanied by grave offerings (Riddell 1978).

Maidu lifestyles were little affected by exploration into mainly Konkow territory by Spanish explorers and missionaries of the early 1800s. Fur trappers and explorers introduced malaria and other diseases including the great 1833 Sacramento Valley epidemic. After the discovery of gold in 1848 at Sutter’s Mill, tens of thousands of gold seekers brought diseases previously unknown in the area. In addition, the concentration and increase in population resulted in the concentration of diseases, decimating the Maidu population. The results were devastating and included the loss of land and territory, including the traditional hunting and gathering locales, violence, malnutrition, and starvation. The Maidu then worked for miners for low wages. The Maidu were forcibly marched to the Round Valley Reservation in 1863, with few provisions or water over a long, hot dry trail. By 1910, estimates indicate the Maidu population had been reduced to only 200 individuals from perhaps 2,300 prior to contact (Kroeber 1925; Riddell 1978).

Today, a small percentage of Maiduan people live on seven Rancherias (Auburn, Berry Creek, Chico, Enterprise, Greenville, Mooretown, and Susanville) and the Round Valley reservation, located in Plumas and Butte counties. The Greenville Rancheria was restored to federal recognition in 1983, and three or four of the original land allotments were also restored to its members. Nearly 200 members are serviced today by this federally recognized group in Greenville, Plumas County.

Historic Period

Early Period, General California History and Specific to the Keddie Ridge Project area
Following the settlement of San Diego in 1769, the Spanish made steady progress in the exploration and settlement of the coastal regions of California. The Central Valley, however, remained largely uncharted. Spaniards made occasional forays into the San Joaquin Valley in pursuit of natives who had fled the forced labor imposed on them at coastal missions. Between 1804 and 1823 the Spanish made numerous trips into the Valley prospecting for new mission sites, attempting to recover stolen horses and cattle, or making punitive raids on the local natives believed responsible for the theft of livestock. In 1820 the Feather River was named by a Spanish exploration party heading up the Sacramento Valley, led by Captain Louis A. Arguello. After spying many waterfowl feathers floating up the water of the river, the party dubbed the watercourse Rio de las Plumas. Subsequent to 1820, Spain's control over California grew ever more tenuous.

A law was passed on September 13, 1813 for secularization of the missions of California. However, at that time there was no expectation that this law would be acted on or enforced (Caughey 1953). That same year Mexican forces prevailed in their struggle for independence and declared California part of the Mexican state. This event marked the beginning of the short-lived Mexican period in California history. Governor Figueroa, by proclamation on August 9, 1834 ordered ten missions secularized. Half the property was to be distributed to the Indians; however, they were not given power to dispose of it and were required to work on "essential community enterprises" (Caughey 1953). The final blow for the missions came in 1844 when Governor Micheltorena ordered the disposal of the remaining mission properties (Caughey 1953). With the decline of the mission came the rise of the ranchos. These Spanish land grants, which were really Mexican, were known as ranchos and encompassed hundreds of acres. Little attention was paid to boundaries (Caughey 1953). The ranchos enriched those fortunate enough to receive one, while effectively subjugating the native labor forces.

Exploration and Settlement

The opportunity to establish an American presence in the interior of California was seized in the decades after Jedediah Smith blazed an overland trail in 1826. Subsequent American settlement of the region was enabled, in large part, by the introduction of exotic diseases that decimated the native populations of California. Early Euro-American pioneers to brave the difficult overland routes to California are exemplified by the Bartleson-Bidwell Party of 1841, the John Work party of 1833 (Englich fir trappers) and the Stevens-Murphey Party of 1844.

In 1839, Swiss emigrant John A. Sutter established a permanent settlement in the Sacramento Valley. In 1841 Sutter applied for and was granted eleven leagues of land near the confluence of the American and Sacramento Rivers where he established the settlement of New Helvetia. In short order he built a small colony which served as the nucleus for economic and political activity in the Sacramento Valley (Hoover et al. 2002). In 1848 Sutter relinquished control of his property to his son, John A. Sutter, Jr.

With the aid of Captain William A. Warner, the younger Sutter laid out the town of Sacramento on the eastern bank of the Sacramento River. That same year gold was discovered in the millrace of Sutter's Mill at Coloma, sparking a massive migration into California as thousands rushed to the goldfields. The California Gold Rush, which fed the economic vitality of northern California, further fueled the decline of the native populations. As thousands rushed to California in search of gold and established businesses, the local indigenous population was overwhelmed and displaced.

In 1848, Peter Lassen and his associate, Isadore Meyerwitz, passed through what is today Plumas County (Fariss and Smith 1882). Later that year Lassen began promoting his route over the Sierra to the goldfields beyond, which traversed Plumas County. The route was variously referred to as Lassen's Cut-off, the Lassen Road, and Lassen's Horn (Fariss and Smith 1882). While many emigrants opted for Lassen's Cut-off in the first year following the discovery of gold at Coloma, prospecting within the streams and rivers of the county would not be successfully conducted until June 1850 (Fariss and Smith 1882). Further down the Feather River, John Bidwell directed a number of Native Americans in his employ to begin working the gravels on his rancho near Chico in 1848, after visiting Coloma (Caughey 1953).

In 1850, Peter Lassen and an associate were the first to establish a settlement in Indian Valley. At the north margin of the valley, immediately south of the Keddie Ridge Project area, they build a small cabin that would serve as a trading post. The men named the broad expanse that lay before them "Caché Valley," although the name did not stick. The Noble party, passing through the area in 1851, referred to the area as "Indian Valley" for the significant population of Maidu people living there. Lassen and his associate took to cultivating the valley and raised a number of vegetables to be sold at their trading post.

In March of 1852 a settlement at Taylorsville was established. During the next few years Indian Valley grew appreciably, and large portions of it were claimed for agriculture. Taylorsville was the site of much of the activity, and it was there that the first sawmill and grist mill were established in the valley in 1855 and 1856, respectively. A private school was opened in 1859, and by 1863 a public school had been built (Fariss and Smith 1882.

Greenville was established to support the thriving quartz mines being operated in its vicinity. The most important mines at the time of Greenville's founding included the Bullion, the Lone Star, and Ellis mines. A four stamp mill was built at Greenville in 1862 by Alfred McCargar, and the town eventually grew up around this location. By 1882 Greenville was home to roughly 500 people and a newspaper, a post office, a church, water-works, a physician, dentist, soda factory, boarding house, barbers, a market, wagon maker, shoemaker, blacksmiths, a sawmill, flour mill, saloons, restaurants, threes stores, and one large hotel (Fariss and Smith 1882). A third town in Indian Valley, Crescent Mills, was established early in the county's history as a quartz mining and processing center. Mining and milling of quartz ore were conducted up until 1926 (Hoover et al. 2002).

Plumas County was organized in 1854, by partitioning Butte County. An official survey and mapping of the recently formed county was authorized in 1871, to be carried out by the County Surveyor, Arthur W. Keddie. Keddie surveyed portions of Plumas County beginning in 1864, including the road between Indian and American Valleys. In addition, he surveyed a projected rail line connecting Oroville to Reno, Nevada. Finally settling in Quincy he served in his official capacity for a number of years (Fariss and Smith 1882).

The population of Plumas County (then still a part of Butte County) grew rapidly following the discovery of gold and the subsequent diversification of the economy. The population of the county in 1860 was 4,554 persons; by 1880 the population had grown by 35 percent to 6,180 individuals (Fariss and Smith 1882). During the 1860 census the population of Indian Valley was reported as 479; this included 362 White, 12 Chinese, and 105 Indian (Fariss and Smith 1882).

Mining in Plumas County

Plumas County has been blessed with an abundance of mineral wealth, which was the impetus for its settlement and early economic development. Mining provided the economic base that allowed other industries, such as agriculture and timber, to evolve in the county. The earliest placers worked in what is now Plumas County include diggings at Nelson's, Poorman's, and Hopkin's Creeks, as well as the vicinity of Rich Bar. Within a few years the easily accessible placer gold deposits were exhausted. New operations sprang up using hydraulic and drift mining techniques, which required much more capital expenditure and expertise. As a result, many of the small mining operations were unable to compete. Many immigrants left the goldfields to seek more steady work in the county's diversifying economy, or to chase new strikes elsewhere, such as the Comstock in Nevada.

Particular to the Keddie Ridge Project area, major gold-bearing quartz ledges were discovered in the Indian Valley area beginning in the early 1860s, which came to be known as the Cherokee Mining District. In 1862 the Green Mountain ledge was discovered near Crescent Mills, which led to greater mineral exploration in the area. The mine was owned by the Green Mountain Gold Mining Company, which also operated the Cherokee Mine near Round Valley and the Gold Stripe mine near Crescent Mills (Fariss and Smith 1882). Mining required a great deal of water, and it was generally supplied by ditches in Plumas County. Fariss and Smith (1882) report that by 1857 there were 45 miles of ditch in the county; by 1880 that figure had reached 1,000 miles county-wide.

Gold mining continued to be the dominant industry in Plumas County until the turn of the twentieth century, when it began to lose ground to other industries such as timber production. Copper deposits discovered in Plumas County in 1865 had not yet begun to turn the economic tide back towards mining due to the relatively low value. Around the turn of the century, the value of copper had increased and one entrepreneurial family was poised to take advantage. The Engels family, led by Henry Engels, had worked for many years to establish a copper mining operation in Lights Canyon, and in 1906 incorporated the Engels Mine. The region experienced a boom in copper production roughly between 1915 and 1930, and Plumas County was the state's largest producer. The Engels Mine proved to be very successful, and led to the construction of the first rail line in Indian Valley. The town of Englemine developed around the operation and was home to roughly 1,200 people in the 1920s. The Engels Mine closed in 1930 (Foote 1991; Smith 1970; Young 2003).

Other significant copper mines operated in the region, notably the Walker Mine. Located about halfway between Grizzly Valley and Genesee, the Walker Mine produced more than $23 million in copper ore in more than three decades of operation. Discovered in 1904, the Walker Mine began producing sizable quantities of copper in 1911. A nine-mile tramway was completed in 1919 to transport ore to a Western Pacific siding in Spring Garden near Quincy. A company town sprang up around the mine, known as Walkermine, owned by the Anaconda Copper Mining Company. The mine and adjacent town went into rapid decline with the sharp drop in copper prices in 1939. By 1941 the mine had shut its doors for good (Bullard-Watson 2006).

Like many places in the Sierra Nevada, Plumas County experienced a resurgence of small-scale gold mining during the Depression. Known as "Snipers", disenfranchised people looking to make enough money to eat, returned to the hills of Plumas County to unearth small amounts of gold. Despite the small resurgence, gold mining never regained the prominent position it once held in the county's economy.

Transportation

In the formative years of the county, there were two primary transportation routes from theCentral Valley to the gold mines and population centers. The two routes are described by Fariss and Smith (1882): "one from Marysville, through Strawberry Valley to Onion Valley, and the Middle Fork of the Feather River, and thence on to American Valley; and one from Bidwell's Bar to Buck's Ranch, Spanish Ranch, American and Indian Valleys, and the mines on the North Fork and East Branch. The former was the first one opened, but the latter has been the most important." The early routes were little more than trails and travel proved difficult. In subsequent years wagon roads were established that made travel easier, thus contributing to the economic health of the area by providing for the transportation of goods. Early wagon roads were private ventures that relied upon tolls to recoup the costs of construction and maintenance. Early notable wagon roads in the region included the Quincy and Spanish Ranch Wagon Road, the Pioneer Wagon Road, the Plumas Turnpike, the Chico and Humboldt Wagon Road, Quincy and Indian Valley Wagon Road, the La Porte and Quincy Wagon Road, and the Red Clover Wagon Road.

In 1849, James Pierson Beckwith (Beckwourth) an African American explorer, was operating a trading post in Sonora, but the next spring he joined the search for a "Gold Lake" said to be somewhere in the northern part of the state. This prospecting trip lead directly to the development of the Beckwourth Trail. In 1850, he discovered a new pass over the Sierra Nevada. In 1854 Beckwith related his life story to Thomas D. Bonner and at the same time changed the spelling of his name to Beckwourth. Crossing the Sierra Nevada was an arduous and dangerous task, so the discovery of the lowest pass across the range, at a mere 5,221 feet in elevation, was an important accomplishment. The Beckwourth Trail branched off from the main California Trail at Truckee Meadows (site of Sparks in Reno, NV) and ended in Bidwell's Bar (mining camp now under waters of Lake Oroville) (Plumas County Visitors Bureau, Oregon-California Trails Association, Plumas National Forest, n.d.).

As mentioned above, the success of the Engels Mine led to the creation of the Indian Valley Railroad, which was built to haul ore from the mine to a siding at Paxton. The standard gauge railroad operated from 1917 – 1938 (Fickewirth 1992). Following the closing of the Engels Mine in 1930, the line continued carrying passengers until 1938. On December 1, 1909, Western Pacific Railroad inaugurated through freight service. Prior to this there had been local freight service between Salt Lake City and Shafter for the Nevada Northern Railroad connecting to the mines in Ely, Nevada. Passenger service did not operate until late summer of that year. There was much fanfare in the towns along the line. DeNevi states that "In Quincy, where the original concept came into fruition, Authur Keddie, now 68 years old almost wept as he spoke in enthusiastic welcome from the courthouse steps" (DeNevi 1978). The Northern California Extension of the Western Pacific Railroad, which was known as the "Inside Gateway," consisted of a 112 mile section through some of the most rugged and isolated sections of California. This section of line between Keddie and Bieber was completed on November 10, 1931 in order to provide the Western Pacific Railroad (in connection with the Great Northern Railroad), a north/south route, competitive with the Southern Pacific Railroad (DeNevi 1978).

Agriculture and Timber Production

After the founding of Taylorsville, agriculture came to play a major role in the economy of Indian Valley. The fertile soil on the valley floor, which was fed by the many tributaries to Indian Creek, had to be reclaimed before farming and ranching could take place on a large scale. By 1853, Indian Valley was on its way to becoming a significant producer of cereal crops as people realized that the mountain valleys of Plumas County were well suited to growing wheat, oats, and barley. By 1855 a variety of agricultural products were being produced by the county including corn, potatoes, hay, butter, cattle, swine, sheep, beer, apples, pears, peaches, and honey (Fariss and Smith 1882). Cattle were raised to provide beef and dairy products. The first flourmill was built in Indian Valley at Taylorsville in 1856, and was followed by a second mill in Greenville.

Timber production in Plumas County dates back to the Gold Rush when wood for flumes, wing dams, and structures was in high demand. The first lumber mill was established by J.B Batchelder at Rich Bar to serve the booming mining community. The development of quartz mines in places like Greenville contributed to the steady demand for the commodity. Early timber operations were small, with a fairly local market (Young 2003).

One of the first companies to acquire significant amounts of timberland in the county was the Reno Mill and Lumber Company, who amassed more than 7,000 acres of forest by 1889 (Young 2003). The industry grew gradually until 1909 when the Western Pacific Railroad was completed in Plumas County and the timber industry expanded rapidly. A number of small, narrow gauge railroad lines were built into the heavily timbered hills of the county to extract the valuable resource. The steam donkey arrived in Plumas County in the early twentieth century, thus making even more timber available for the busy mills. From that point on, timber was the dominant industry in the county and continues to be an economic force to this day (Young 2003).

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

Regulatory Environment

Section 110 of the National Historic Preservation Act (NHPA) requires the federal government to preserve important historic, cultural, and natural aspects of our national heritage. To accomplish this, federal agencies use the Section 106 process associated with the National Historic Preservation Act (NHPA). Passed by Congress three years before the National Environmental Policy Act (NEPA), the NHPA sets forth a framework for identifying and evaluating historic properties and assessing effects on these properties. This process has been codified in 36 Code of Federal Regulations (CFR) 800 Subpart B. The coordination or linkage between the Section 106 process of the NHPA and the mandate to preserve our national heritage under NEPA is well understood and is formally established in 36 CFR 800.3b and 800.8.

NEPA includes reference to "... important historic, cultural, and natural aspects of our national heritage." This terminology includes those resources defined as "historic properties" under the NHPA (36 CFR 800.16(l)(1)). Therefore, agencies use the NHPA Section 106 process to consider, manage, and protect historic properties during the planning and implementation stages of federal projects. The Plumas National Forest uses the Regional Programmatic Agreement (RPA) to implement the Section 106 process.

Additional direction is provided by *Interim Protocol for Non-Intensive Inventory Strategies for Hazardous Fuels and Vegetation Reduction Projects Annex to Stipulation IX in the First Amended Regional Programmatic Agreement (June 2004).*

Effects Analysis Methodology

Specific Methodology

The heritage resources geographic analysis area is the Keddie Ridge Project area (6,160 acres)., also the Area of Potential Effect (APE). Area of potential effects as defined by 36CFRPart 800.16(d) means the geographic area or areas within which an undertaking may directly or indirectly cause alterations in the character or use of historic properties, if any such properties exist. The area of potential effects is influenced by the scale and nature of an undertaking and may be different for different kinds of effects caused by the undertaking. An Undertaking as defined by 36CFR800.16(y) means a project, activity, or program funded in whole or in part under the direct or indirect jurisdiction of a Federal agency, including those carried out by or on behalf of a Federal agency; those carried out with Federal financial assistance; and those requiring a Federal permit, license or approvalThis boundary was chosen because sites within the Keddie Ridge Project area would be protected during the implementation of the action activities. The temporal boundary is determined by the life of the project. This boundary was chosen because sites within the Keddie Ridge Project area would be protected during the implementation of any of the action activities.

Three levels of analyses were completed to understand the significant themes and extent of heritage resources associated with the Keddie Ridge Project. First, research into the greater history of the Keddie Ridge Project area was conducted to understand historic themes or events that have transpired in time and space (refer to the "History of the Project Area" section above). Second, a heritage resource survey was conducted for the Keddie Ridge Project area to identify heritage properties associated with these themes. Lastly, heritage properties were assessed to determine potential effects associated with implementation of the project. The results and relevant rationale for each of these analyses are presented below. Inventory survey methodology consisted of pedestrian transect spacing of 0-20 meters (Complete), 20-40 meter transects (General), and 40-60 meter transects (Cursory).

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past

actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.”

Affected Environment

The majority of the Keddie Ridge Project area was previously surveyed during thirty three earlier projects (3,742 acres). The remaining 2,418 acres of the Keddie Ridge Project area were inventoried in 2006, 2007, and 2010 by Pacific Legacy Inc., the Plumas National Forest, and TEAMS Enterprise. Based on previous studies and the inventories conducted for this undertaking, the entire area has been adequately assessed for heritage resources. All identified heritage resources have been fully recorded and are on file at the Mt. Hough Ranger District office.

There are a total of forty-seven known heritage resource sites (historic properties) located within the Keddie Ridge Project area. Thirty-six of these sites are located within proposed treatment units. Ten sites are not located within treatment units but are located within the Keddie Ridge Project area. One site is located both within and outside of a Treatment Unit and is also located within the Project area. Of the 47 known heritage resource sites, three are classified as prehistoric; one is classified as multi-component (both prehistoric and historic attributes); and 43 sites are classified as historic. The prehistoric sites consist of bedrock mortars, a traditional bear grass gathering site, and a village site. The multi-component site consists of house depressions and a historic artifact concentration. The historic sites consist mainly of artifacts and features associated with mining activities that took place within and adjacent to the project area. All known heritage resources within the Keddie Ridge Project area of potential effect (APE) were field visited and the site boundaries flagged with the exception of three sites within three of the treatment units.

Treatment units 68, 72 and 79 are slated for hand thinning, piling and burning. Two of the units contain large mining complexes and one of the Units contains a town site. Within these large historic sites, there are areas devoid of heritage features where hand piles can be carefully placed without affecting the integrity of the heritage resources. Each of the features has been flagged for avoidance within the heritage resource site boundaries. In addition, an Archaeologist from the Mt. Hough Ranger District Heritage Resources Staff will be on site monitoring placement of hand piles within Units 68, 72 and 79. Vegetation treatment within site boundaries is allowed under certain conditions stated in the *Standard Resource Protection Measures V.B.8, Interim Protocol for Non-Intensive Inventory Strategies for Hazardous Fuels and Vegetation Reduction Projects* (June, 2004). A total of 53 isolated finds were recorded in 2006 and in 2010. Isolated finds are not heritage resource sites (historic properties) and therefore require no protection. Isolated finds are defined as single artifacts, a small group of a few artifacts no associated with a larger heritage resource site or single archaeological features.

Native American Consultation

Consultation was initiated on March 31, 2010 with the following tribes: Honorable Gary Archuleta (Chairman, Concow Maidu tribe of Mooretown Rancheria), Honorable Glenda Nelson (Chairwoman, Estom Yumeka Tribe of Enterprise Rancheria), Honorable Kyle Self (Chairman, Greenville Indian Rancheria), Honorable Stacy Dixon (Chairman, Susanville Indian Rancheria), Honorable Jim Edwards (Chairman, Tyme Maidu Tribe of Berry Creek Rancheria), and the Honorable Waldo Walker (Chairman, Washoe Tribe of Nevada and California). In addition, consultation was initiated with Lorena Gorbet (Chairwoman, Maidu Cultural and Development Group).

Responses to Native American Consultation

Responses were received from Mike DeSpain, (Director of the Office of Environmental Plannning and Protection, Mechoopda Indian Tribe of Chico Rancheria, California), Melany Johnson (Tribal Historic Preservation Officer, Susanville Indian Rancheria) and Ren Reynolds (Environmental Coordinator Estom Yumeka Tribe of Enterprise Rancheria).

Herbicide Use on Basketry Material Collectors

On June 10, 2010, a field trip to the Keddie Ridge Project area was undertaken. Two heritage resource sites were visited and the boundaries re-flagged at this time.

There is one known bear grass location south of Canyon Dam. No herbicides will be applied in or around the Canyon Dam bear grass areas. No other plant collection areas are known in the Keddie Ridge Project area. No weed infestations have been documented within Bear Grass collecting sites.

The hazards associated with the proposed herbicides and fungicide (aminopyralid, glyphosate, and borax) have been compiled in a group of risk assessments completed by Syracuse Environmental Research Associates (SERA 2003, 2006, 2007) and are incorporated by reference into this section. This risk assessment was completed for the entire USDA Forest Service. In addition, Appendix I presents project-specific results from an analysis conducted for the Keddie Ridge Project to further characterize the risk of herbicide exposure to members of the general public. One of the scenarios that produced a hazard quotient above one (i.e. had an elevated level of risk) was one that involved the consumption of glyphosate-contaminated vegetation. Under normal circumstances, particularly in the case of noxious weed treatment applications, it is extremely unlikely that humans will consume, or otherwise place in their mouths, vegetation contaminated with the proposed herbicides. One exception to this could be plants collected by Native Americans for basket weaving or medicinal use. However, in most instances, particularly for longer-term scenarios, treated vegetation would probably show signs of damage from herbicide exposure, thereby reducing the likelihood of consumption that would lead to significant levels of human exposure. In addition, there are no individuals with permits to collect in these areas, which further reduces the risk of exposure. Signs may also be posted prior and post herbicide application. All relevant federal, state, and local laws will be followed with respect to herbicide application. For a complete discussion of the risks associated with the proposed chemicals, refer to Appendix I.

Environmental Consequences

Direct and Indirect Effects (All Action Alternatives)

Heritage Resource site boundaries are flagged and the Standard Resource Protection Measures as outlined in the RPA (March, 2001) would be followed during implementation of any of the Action alternatives (Alternatives A, C, D and E). All artifacts and features would be avoided during project implementation therefore there would be no effect to heritage resources.

Cumulative Effects (All Action Alternatives)

Heritage resource sites will be protected using Standard Resource Protection Measures as outlined in the RPA. However, by protecting heritage resource sites from fuel treatments under all action alternatives, there may be a cumulative effect of creating islands of un-thinned, unburned fuels. These islands may burn hotter and longer that treated areas in the event of a fire.

In general, past, present and foreseeable future events have had cumulative effects of varying degrees on heritage resources. There is no substantive difference in cumulative effects predicted for heritage resources between the alternatives.

Alternative B – No Action Alternative

Direct and Indirect Effects

No project treatment activities would occur under the no action alternative; hence, there would be no effects on heritage resources.

Cumulative Effects

No project treatment activities would occur under the no action alternative; hence, there would be no effects on heritage resources.

Compliance with the Forest Plan and Other Direction

The effects of the project on heritage resource sites were assessed in compliance with Section 106 of the National Historic Preservation Act as mended (1966).

No effects are anticipated, since the following Standard Resource Protection Measures (SRPMs), *First Amended Regional Programmatic Agreement* (March, 2001) and *Interim Protocol for Non-Intensive Inventory Strategies for Hazardous Fuels and Vegetation Reduction Projects Annex to Stipulation IX in the First Amended Regional Programmatic Agreement* (June, 2004) would be implemented, as appropriate, for all heritage resources within the Keddie Ridge Project area that could potentially be affected by project implementation. Application of the following SRPMs would result in the project having "no effect" on heritage resources (*First Amended Regional Programmatic Agreement* (March, 2001):

- All proposed activities, facilities, improvements, and disturbances shall avoid heritage resource sites. Avoidance means that no activities associated with the project that may affect heritage resource sites shall occur within a site's boundaries, including any defined buffer zones. Portions of the project may require modification, redesign, or elimination to properly avoid heritage resource sites.
- All heritage resource sites within the area of potential effect shall be clearly delineated prior to implementing any associated activities that have the potential to affect heritage resource sites.
- Buffer zones may be established to ensure added protection where the Forest or District Archaeologist determines that they are necessary. The use of buffer zones in conjunction with other avoidance measures are particularly applicable where setting contributes to the property's eligibility under 36 CFR 60.4, or where it may be an important attribute of some types of heritage resource sites (e.g., historic buildings or structures; historic or heritage properties important to Native Americans). The size of buffer zones needs to be determined by the Forest or District Archaeologist on a case-by-case basis.
- When any changes in proposed activities are necessary to avoid heritage resource sites (e.g., project modifications), these changes shall be completed prior to initiating any activities.
- Monitoring during project implementation, in conjunction with other measures, may be used to enhance the effectiveness of protection measures.

From *Interim Protocol for Non-Intensive Inventory Strategies for Hazardous Fuels and Vegetation Reduction Projects Annex to Stipulation IX in the First Amended Regional Programmatic Agreement* (June, 2004):

- All heritage resource sites within the area of potential effect shall be clearly delineated prior to implementing any associated activities that have the potential to affect heritage resource sites.
- Buffer zones may be established to ensure added protection where the Forest or District Archaeologist determines that they are necessary. The use of buffer zones in conjunction with other avoidance measures are particularly applicable where setting contributes to the property's eligibility under 36 CFR 60.4, or where it may be an important attribute of some types of heritage resource sites (e.g., historic buildings or structures; historic or heritage properties important to Native Americans). The size of buffer zones needs to be determined by the Forest or District Archaeologist on a case-by-case basis.
- Fire crews may monitor sites to provide protection as needed.
- Fire lines or breaks may be constructed off sites to protect at risk historic properties.

- Vegetation may be removed and fire lines or breaks may be constructed within sites using hand tools, so long as ground disturbance is minimized, and features are avoided, as specified by the Heritage Resource Manager.
- Fire shelter fabric or other protective materials or equipment (e.g., sprinkler systems) may be utilized to protect at risk historic properties.
- Fire retardant foam and other wetting agents may be utilized to protect at risk historic properties and in the construction and use of fire lines.
- Surface fuels (e.g., stumps or partially buried logs) on at risk historic properties may be covered with dirt, fire shelter fabric, foam or other wetting agents, or other protective materials to prevent fire from burning into subsurface components and to reduce the duration of heating underneath or near heavy fuels.
- Trees which may impact at risk historic properties should they fall on site features and smolder can be directionally felled away from properties prior to ignition, or prevented from burning by wrapping in fire shelter fabric or treating with fire retardant or wetting agents.
- Vegetation to be burned shall not be piled within the boundaries of historic properties unless the location (e.g., a previously disturbed area) has been specifically approved by the Forest’s HRM.
- Mechanically treated (crushed/cut) brush or downed woody material may be removed from historic properties by hand, through the use of off-site equipment, or by rubber-tired equipment approved by the HRM. Ground disturbance shall be minimized to the extent practicable during such removals.
- Woody material may be chipped within the boundaries of historic properties so long as the staging of chipping equipment on-site does not affect historic properties.
- The Forest’s HRM shall approve the use of tracked equipment to remove brush or woody material from within specifically identified areas of site boundaries under prescribed measures designed to prevent or minimize effects. Vegetative or other protective padding may be used in conjunction with the HRM’s authorization of certain equipment types within site boundaries.

Recreation

Introduction

The purpose of this section is to present a summary of the effects of the proposed project on developed and dispersed recreation. Less than one percent of the proposed Keddie Ridge Hazardous Fuels Reduction Project area falls within recreation areas. The Recreation Opportunity Spectrum (ROS) is used as an indicator to measure beneficial or adverse effects on recreation. The ROS class for areas within the recreation analysis area is identified in the Plumas National Forest Land and Resource Management plan (PNF LRMP) (USDA 1988).

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

Regulatory Environment

Federal Laws

Travel Management Rule

The 2005 Travel Management Rule requires that in designating National Forest System (NFS) roads, trails, and areas, responsible officials consider the provision of recreational opportunities; public access needs; conflicts among uses of NFS lands, including other recreational uses; and the compatibility of motor vehicle use with existing conditions in populated areas (36 CFR Part 212, Subpart B).

Forest Plan

The 1988 PNF LRMP provides goals, objectives, and management direction for recreation activities on the Plumas National Forest. The PNF LRMP was amended by the 1999 Record of Decision on the Herger-Feinstein Quincy Library Group Forest Recovery Act Final Environmental Impact Statement (EIS) and the 2004 Record of Decision on the Sierra Nevada Forest Plan Amendment Final Supplemental EIS. The PNF LRMP identifies standards and guidelines for the Indian Valley area, Round Valley Lake, and Keddie Ridge Restricted Vehicle Access Area. The actions proposed for the Keddie Ridge Project would need to meet PNF LRMP standards and guidelines in order to maintain recreational opportunities. The 1988 PNF LRMP classifies recreational opportunities for the Forest under the Recreation Opportunity Spectrum (ROS). ROS classes in the project area include “Semi-Primitive Non-Motorized,” “Roaded Natural,” “Rural,” and the majority of the project area falls under “Roaded Modified.” The existing condition of the landscape for the recreation analysis area is described in the “Forest Vegetation, Fire, Fuels, and Air Quality” section of this DEIS. Past management activities are common where recreation occurs, but a naturally appearing landscape still dominates the project area.

Sierra Nevada Forest Plan Amendment: Final Supplemental Environmental Impact Statement Record of Decision: Forestwide Standards and Guidelines (2004)

There are no Forest-wide standards and guidelines from SNFPA 2004 that are applicable to recreation.

Specific Methodology

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.(Refer to appendix F for past, present and future projects).

The geographic area analyzed for effects on recreation is the area in the immediate vicinity of the treatment units, haul routes, and roads proposed for reconstruction. The recreation analysis area boundary incorporates campgrounds, dispersed recreation areas, roads, trails, lakes, creeks, and vegetative landscape that could be affected by the activities listed under each alternative.

Data Sources

All the data displayed in the recreation analysis was obtained from the special use permit files, National Forest System records (trails, roads, etc.), and corporate and project GIS data (treatment areas, prescriptions, etc.) which is stored at the Mount Hough Ranger District.

Affected Environment

The Greenville Campground, and Indian Falls Interpretive Trail are developed recreation sites within the project area, but they are not in the vicinity of any treatment units and therefore will not be analyzed in this document. The Round Valley Recreation Area and the Peters Creek Trail are developed recreation sites within the recreation analysis area. The Round Valley Recreation Area has a “Roaded Natural” ROS class. The Roaded Natural ROS class is: “a predominately natural environment where resource modification and utilization practices are evident. Evidence of the sights and sounds of man is moderate and in harmony with the natural environment. Opportunities exist for both social interaction and moderate isolation from sights and sounds of man” (USDA 1988). The Peters Creek Trail area has a “Roaded Modified” ROS class. The LRMP defines the Roaded Modified ROS class as: “those Roaded Natural areas that are also coded as Middleground, Background or Unseen, and Sensitivity Level II or III. This is the general resource management area of the Forest, typified by pick-up trucks and many miles of dirt and gravel roads. Other than trails and trailheads, virtually no improvements are present. Users experience low interaction” (USDA 1988).

The Round Valley Run, Indian Valley Century Bike Ride, and the Patriots Day Ride are three permitted, annual recreation events that occur partially or entirely within the project area. The Round Valley Fishing Derby is a Forest sponsored event.

- Round Valley Run/Walk-foot Race – The event route is around Round Valley Lake (5.3 miles) and also includes a walk along County Road 204 for two miles. This one day event date is scheduled for August and involves approximately 100 participants and hosts approximately 30 spectators.
- Indian Valley Century Bike Ride – This 100 mile bike ride begins in Greenville, continues to Genessee Valley, then to Boulder Creek Work Station and returns to Greenville. This one day event is scheduled for May, and involves approximately 100 participants and hosts approximately 40 spectators.
- Patriots Day Ride - This is a 100 mile horse endurance ride. This event is scheduled for September. and involves approximately 60 participants and 50 spectators. This event operates on existing Forest System roads and trails and is spread over two days. The event course will take place on both the Mount Hough and Almanor Ranger Districts, the latter of which is on the Lassen National Forest.

Currently there are 39 special use permits within the project area that include: road easements, power lines, railroad right-of-ways, waterlines, telephone lines, barn/shed, private residences, irrigation ditches, transfer stations, livestock areas, natural resource monitoring, weather stations, weather modification devices, storage yards, industrial microwaves, a campground concession permit, and recreation events. Most special use permits require maintenance of the permitted area by permittees and include activities such as hazard tree removal, brush removal, road and improvement maintenance.

Dispersed recreation activities within the recreation analysis area include camping, hiking, swimming, boating, fishing, wildlife watching, horseback riding, mountain biking, off-highway vehicle (OHV) use, snowmobile riding, ice skating, hunting, rock hounding, driving for pleasure, Christmas tree cutting, and firewood cutting.

There are two non-motorized system trails within the recreation analysis area, the Peters Creek Trail and the Round Valley Interpretive Trail. Annual trail maintenance work consists of logging out, maintaining water bars or other erosion control devices, and maintaining and replacing signs. Work is typically accomplished by Forest Service crews and volunteers.

Woodcutting for personal and commercial use is permitted throughout the recreation analysis area. In the past nine years it is estimated that approximately 20 percent of the Mt. Hough Ranger District’s fuel wood permit sales are within the project area. Approximately 25 percent of the Christmas tree cutting is within the project area.

Environmental Consequences

Alternative B – No Action

Direct Effects

There would be no direct effects on recreation under this alternative because there would be no change in current recreation opportunities or ROS classifications.

Indirect Effects

Alternative B would not cause any short-term indirect effects on recreation opportunities. However, taking no action could result in long-term effects on recreation opportunities due to the increased risk of large-scale wildfires and reduced forest health, which could degrade scenic landscapes within recreation areas.

In the absence of the proposed treatments, forested stands would continue to grow and become dense, resulting in increased fuels accumulation and elevated risk of severe wildfire. Depending on the scope and severity of a wildfire, this type of event could cause temporary or long-term closures to recreation areas and inconvenience the recreation user. In the worst case, fire damage could be so extreme that recreation areas could take several decades to recover; these situations could result in displacement of forest visitors due to destruction of recreation facilities or loss of access to trailheads and dispersed or developed campgrounds.

Past observations on the Plumas NF suggest that large-scale fires could have adverse effects on recreation opportunities for 20 to 30 years. For example, areas that burned in the recent Moonlight Fire near Antelope Lake can still be seen from Forest System roads and campgrounds. Vegetation in these areas has been slow to return and has created a barren-looking landscape. Corrals at the Antelope Trailhead were burned by the fire and fallen snags along the trail prevented equestrians and mountain bikers from using the trails for a several years until crews finished restoration work

Reduced forest health in over stocked stands can result in insect infestations which create hazard trees as well as diminish aesthetic values.

Alternatives A, C, D, and E

Direct Effects

The four action alternatives are very similar in their effects on recreation resources. Although alternatives A and D propose the use of two herbicides and a fungicide, the risk to Forest visitors is expected to be negligible. The Human Health Risk Assessment, completed for the Keddie Ridge Project (appendix I), provides a detailed summary of the low risk that these chemicals present to human health and safety. The ROS Roaded Natural and Roaded Modified both allow for resource modification and utilization practices being evident, therefore the ROS classification would not be directly effected.

Developed Recreation

All of the action alternatives would result in minor direct effects on developed recreation areas at Round Valley Reservoir. There is a total of 134 acres of mechanical and hand thinning treatments proposed around the Round Valley Reservoir (units 72, 73, 74, and 107). These treatment activities would require an increased presence of heavy equipment and logging trucks on National Forest System roads; however signs would be posted to alert visitors of potential safety hazards. The Interpretive Trail at Round Valley Reservoir would be closed temporarily during the treatment activities. Signs will be posted in advance to notify the public. Heavy equipment and logging trucks may be noisy at times, which could have a minor temporary effect on a visitor’s opportunity for a peaceful recreation experience.

Dispersed Recreation

The action alternatives would result in minor short-term direct effects on dispersed recreation activities. A total of 136 acres of treatment are proposed around the Peters Creek Trail (unit 84); treatments include hand thin, underburn, and herbicide application. The trail system would be closed for the duration of the treatment activities. Advanced placement of warning signs as a safety precaution would help reduce any potential impacts on recreation users. Treatment activities would have long-term beneficial effects on the Peters Creek trail by helping to reduce fuels buildup, reduce debris along the trail and improve forest health

Project implementation activities could displace visitors seeking to use dispersed camping areas or day use areas. This is considered a minor short-term effect since visitors could use other areas of the Forest. Advanced placement of signs as safety precaution would help reduce any potential impacts on recreation users.

Existing NFS maintenance level 2 roads within the recreation analysis area would be used during operations as haul routes. Currently these routes are open to all vehicles. Prior to operations these routes may be improved to facilitate logging trucks. These improvements are not expected to diminish the recreation experience, and would have a beneficial effect on the NFS roads within the recreation analysis area. The impacts to recreational users during operation on these roads would be temporary road closures, increased traffic, dust, and noise. Signs would be posted in advance to notify the public and help avoid any potential impacts on recreation users. This is considered a minor short-term effect since visitors can use other areas of the Forest.

Portions of NFS road 28N38A (0.6 miles) and non-system road (continuation of 28N38A) (0.4 miles) are proposed for decommissioning. The routes decommissioned with the Keddie Ridge Project would remain closed to all motorized traffic. These routes are not OHV routes and decommissioning them would not have any effect on recreation and minimal impacts on public access due to the fact that it is a small dead end spur.

Indirect Effects

The proposed treatments would reduce hazardous fuels and create a more diverse and fire-resilient forest, which would have an overall beneficial effect on recreation opportunities by helping to maintain and preserve the landscape of existing recreation sites and areas. Reducing hazardous fuels adjacent to Round Valley Picnic Area and Peters Creek Trail would likely reduce the risk of a wildfire that could threaten existing improvements. Reducing the risk of wildfire would help ensure that recreation opportunities for developed and dispersed recreation would be maintained at existing conditions.

Underburning in treatment units could cause short-term negative effects on visual quality in developed and dispersed recreation areas. Smoke caused by underburning could also affect recreation events such as the Round Valley Run, Indian Valley Century Bike Ride and Patriots Day ride; however these three events happen in May, August and September, when burning is generally prohibited or considered infeasible. Herbicide applications would not cause any indirect effects on recreation users and are expected to present a low risk to human health and safety as demonstrated in the Human Health Risk Assessment (Appendix I).

Cumulative Effects

Alternatives A, C, D, and E would have no long-term cumulative effects on recreation resources in the recreation analysis area. Although effects of past vegetation management activities are common in the recreation analysis area, the proposed DFPZ, area thinning, group selection, and fuels treatments would have minor long-term beneficial effects on meeting the desired conditions for recreation opportunities. The desired conditions are to provide forest-related recreation for the public with facilities: preserve, protect or improve the surrounding forest around all recreation sites. There may be minor short-term effects on view sheds from campgrounds, trails, or roads, but long-term effects would meet forest standards and guidelines for identified ROS classes. Future vegetation management projects in the recreation analysis area would likely reduce hazardous fuel conditions that could threaten recreation areas, facilities, and view sheds.

The thinning activities would have a beneficial effect of reducing the risk of wildfire and aesthetically improving the stands of trees. Improving forest health would insure that this area remains well stocked and pristine. These values promote and benefit recreation.

Range

Introduction

The range resource encompasses permitted livestock that are authorized to graze within an allotment boundary through a ten year Term Grazing Permit issued by the Forest Service. Included in the range resource are:

- permitted livestock;
- range improvements needed to manage the allotment including fences, gates, exclosures, cattle guards and water developments;
- the permittee, that is, the rancher who owns and manages the cattle;
- creeks and springs from which livestock drink;
- and forage (grass, forbs, and shrubs) eaten by permitted livestock.

Analysis Framework: Statute, Regulatory Environment, Forest Plan, and Other Direction

Regulatory Environment

The guidance for range management is provided in the Plumas National Forest Land and Resource Management Plan (PNF LRMP) (USDA 1988) as amended by Herger-Feinstein Quincy Library Group (HFQLG) Final Supplemental Environmental Impact Statement (FSEIS) and Record of Decision (ROD) (USDA 1999a, 1999b, 2003a, 2003b), and the Sierra Nevada Forest Plan Amendment (SNFPA) FSEIS and ROD (USDA 2004a, 2004b).

Effects Analysis Methodology

The analysis area for direct, indirect, and cumulative effects on range resources includes the Lights Creek Allotment. Effects were not considered for the Taylor Lake Allotment, which is currently vacant.

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past

actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, “agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.

Affected Environment

The Plumas National Forest is divided into 67 allotments. An allotment is an area of land that has been designated for the permittee to graze their cows. The area of land contains both primary and secondary range. Primary range is land that is less than 40 degrees slope and produces more than 200 pounds of forage per acre. Secondary range is the timbered areas within an allotment. Transitory range can be created when timbered areas are treated. Keddie Ridge Project treatment areas are located in secondary range. There are no range improvements in the Keddie Ridge Project area.

The Lights Creek Allotment is 9,612 acres. The overlap with the Keddie Ridge Project is 678 acres (Figure 24). The Lights Creek Allotment is considered small for the Plumas National Forest. An average allotment on the east side of the forest characterized by more open timbered East Side Pine type vegetation and flatter ground grazes about 200 cattle pair during a four month season. The Lights Creek Allotment grazes only 24 pair (On) and 16 pair (Off) with a three month season. An On/Off permit grazes Natioanl Forest System lands as ‘On’ and leased private lands as ‘Off’. Only limited use has occurred in the treatment area. Use has not been monitored or reported within the treatment area because it is not primary range.

The current permittee has been grazing the same herd, with replacement heifers on this allotment for decades. With the current permittee, the cows tend to use the northern portion of the allotment because it is flatter, has meadows, and ties in with his adjacent allotment on the adjacent Lassen National Forest to the north of the project area. The portion of the allotment the cows use is approximately 4 miles from the treatment area. Figure 24 shows the spatial relationship between the project area, the allotment boundary, and the monitoring area. The cows tend to prefer meadows over timbered areas and therefore tend to use the project area very little because it is timbered. The monitoring area for the Lights Creek Allotment is Indicator Meadow, which is approximately 4 miles north of the project area (Figure 24).

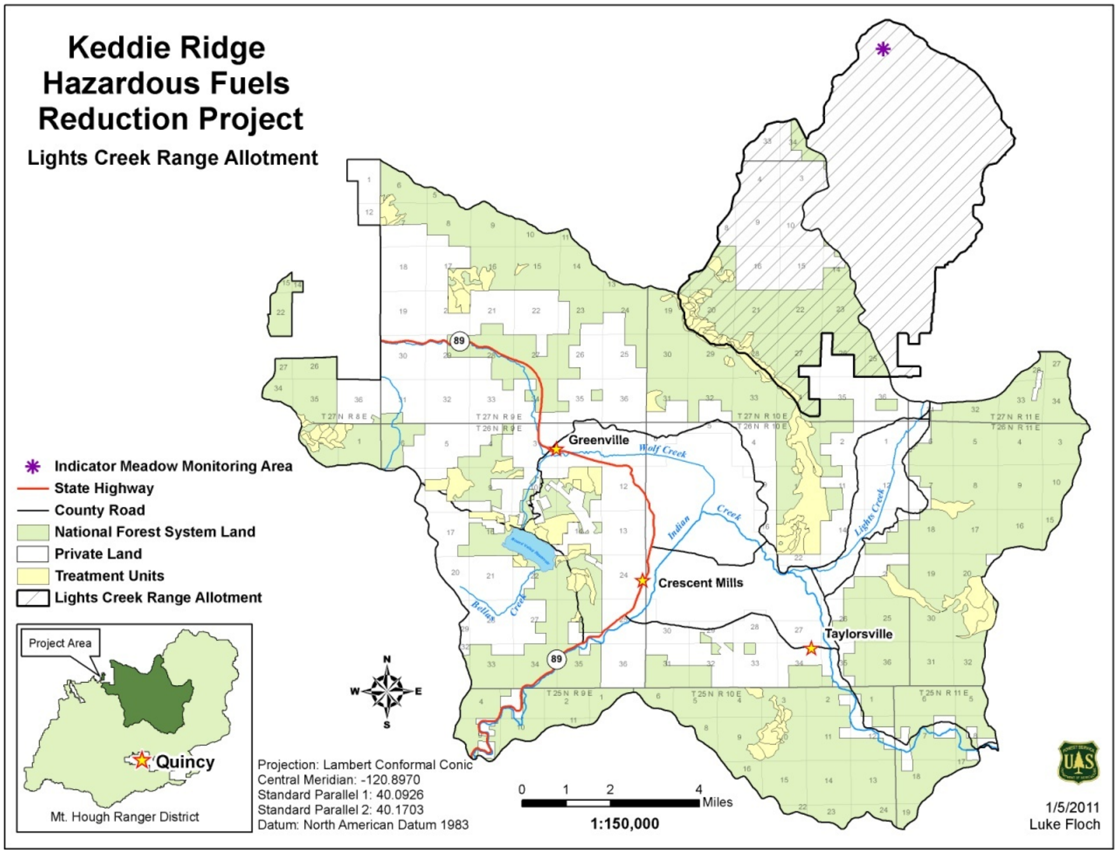

Figure 24. Map of Lights Creek Allottment, Keddie Ridge Project Area, and Indicator Meadow Monitoring Area

Environmental Consequences

Alternatives A, C, D, and E

Direct and Indirect Effects

Alternatives A, C, D, and E would have minor short-term direct effects on range resources. The Lights Creek Allotment would continue to be managed at current levels. Direct and indirect effects of hand thin, mechanical thin, group selection, mastication, and prescribed fire treatments to permitted cattle are displacement from the noise and activity. Since cattle use in the treatment areas is minimal, there will be little short-term displacement. Area thinning, group selections, and DFPZ units that involve timber falling and prescribed burning would require coordination between the Forest Service range specialist and the range permittee to ensure that livestock are kept away from active operations.

There could be an increased risk of vehicle collisions with livestock on haul routes and access roads to the treatment areas. Vehicle collisions could be avoided by ensuring that contracts contain safety specifications for traffic and by alerting contractors where cattle may be present.

The herbicide treatments proposed in alternatives A and D would have negligible adverse indirect effects on livestock. Although the potential is low (since livestock do not typically graze on noxious weeds, such as starthistle or Canada thistle), it is possible that livestock could consume vegetation contaminated by glyphosate or aminopyralid. In order to quantify the potential effect on livestock, a scenario was analyzed to examine chronic or longer-term exposure to contaminated vegetation with both proposed applications of pesticides for glyphosate and aminopyralid (SERA 2003, 2007). The level of risk was determined by using a "Hazard Quotient," which is calculated based on proposed application rates. A Hazard Quotient of less than one is considered to be a low risk. The results of this analysis are presented in Table 91. These results indicate that the Hazard Quotients for applications of glyphosate and aminopyralid would be less than one; therefore, the risk to livestock exposed over the long-term to glyphosate or aminopyralid would be low.

Table 91. Scenario Involving Long-Term Exposure of a Large Mammal to 100 Percent Contaminated Vegetation

Herbicide Scenario (long-term exposure to contaminated vegetation)	Hazard Quotient		
	Central	Lower	Upper
Aminopyralid	0.002	0.0002	0.03
Glyphosate	0.05	0.006	0.5

Sources: SERA 2003, 2007

Herbicide labels and Human Health and Ecological Risk Assessments Final Reports for aminopyralid, glyphosate, and borax were reviewed for the Keddie Ridge Project. There are no label restrictions for range cattle. Since there are no label restrictions for range cattle, Hazard Quotients are low, and livestock use within the treatment area is limited, there will be negligible direct or indirect effects to permitted livestock. The District will coordinate treatments with Forest Range Staff who will let the permittee know when treatments are planned.

Cumulative Effects

Alternatives A, C, D, and E would not contribute to adverse cumulative effects on range resources. Past, present and future vegetation management activities (listed in appendix F) have and would continue to help maintain or improve transitory range. The proposed area thinning treatments combined with future vegetation management projects would help maintain transitory grazing opportunities for livestock. Future DFPZ maintenance would continue to allow short-term opportunities for openings and transitory rangelands.

Alternative B No Action

Direct and Indirect Effects

There would be no adverse effects on range resources under the no action alternative. The Lights Creek Allotment in the Keddie Ridge Project area would continue to be managed under current direction and guidelines in the Forest Plan.

The short-term benefits of taking no action would be that the permittee or their livestock would not be affected by project activities.

There could be minor short-term indirect effects on suitable habitat without the underburning treatments, since burning helps encourage growth of available forage (grasses). Without implementing area thinning treatments, there could be long-term minor effects on range resources through decreased suitable habitat.

In the absence of noxious weed treatments, it is possible that noxious weed populations could spread and have long-term effects on available native forage species. However, without herbicide use, there would be no risk of exposing cattle to herbicide spills or vegetation that has been treated with herbicides.

Cumulative Effects

Alternative B could increase the potential short-term cumulative effects on range resources. The risk of future fires causing damage to forage would be a short-term effect on grazing because forage would return after a fire. Cows may need to be temporarily removed for one to three years until new vegetation and soils are better stabilized.

Minerals

Introduction

There are approximately 168 active mining claims in the Keddie Ridge Project area[9]. The Mt. Hough Ranger District currently administers three active plans of operation and four notices of intent for active mining claims in the project area. In addition, there are 5 claims for which plans have been submitted and completed, but are on hold by the owner operator. These could be activated at any time. This area has a long history of mining. There are several claims which are not currently being worked but which may be worked in the future. There are two abandoned mines in the project area that may be identified for closure next year. Many more exist but are not yet identified.

This mining analysis includes the effects of the Keddie Ridge Project on mining claimants and mine operators. The short-term and long-term effects, including beneficial effects, are included in this analysis.

[9] http://www.blm.gov/lr2000/

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

Regulatory Environment

Federal Laws

Management of mining operations on the Plumas National Forest falls under several regulatory authorities. The Mining Law of 1872 established the category of locatable minerals. It authorized placer and lode mining claims, mill site claims and tunnel site claims and modified the ability for patenting upon proven discovery. It also required at least $100 worth of work on each claim annually in order to maintain a possessory title.

The Forest Service Organic Administration Act of 1897 gave the Forest Reserves the basic authority to regulate surface uses, including mining.

Other regulatory Acts which affect minerals administration on the Forest include the 1947 Materials Act, the 1955 Multiple Use Mining Act (Surface Use Act), and the Clean Water Act, Section 401.

Daily operations are regulated under 36 CFR 228 regulations, Subpart A and Subpart C.

State Laws

The California Surface Mining and Reclamation Act of 1975 (SMARA) requires that anyone, including government agencies, engaged in surface mining operations in California (including those on federally managed lands) which disturb more than one acre or remove more than 1,000 cubic yards of material must submit and be subject to a Reclamation Plan. This includes, but is not limited to: prospecting and exploratory activities, dredging and quarrying, streambed skimming, borrow pitting, and the stockpiling of mined materials.

Mining operators are responsible for the preparation and submission of reclamation plans and financial assurances for reclamation to the lead agency. Annual reporting to both the State and the lead agency on the status of mining and reclamation activities, annual updates of financial assurances, and annual inspections (to be conducted under the auspices of the lead agency), are required. Following completion of mining activities, and in accordance with the approved reclamation plan and relevant permit conditions, mining operators return mined lands to a second, productive use. Examples of post-mining uses may include, but are not limited to, open space, wildlife habitat, agricultural lands, grazing, park lands, and preparing the land for industrial or commercial uses[10].

Forest Plan

Herger-Feinstein Quincy Library Group Forest Recovery Act

No specific references to mineral and geology resources are made within the HFQLG Forest Recovery Act.

Herger-Feinstein Quincy Library Group Forest Recovery Act EIS, Supplemental EIS, Records of Decision (1999 and 2003) and Appropriations Acts

No specific references to mineral and geology resources are made within the HFQLG Forest Recovery Act EIS, Supplemental EIS, Records of Decision (1999 and 2003) and Appropriations Acts.

---

10 http://www.consrv.ca.gov/omr/smara

Sierra Nevada Forest Plan Amendment Final Supplemental EIS (2004)

The Sierra Nevada Forest Plan Amendment (2004) expands upon direction outlined in the Forest Plan and further delineates standards and guidelines for mining with requirements for reclamation, inspections and monitoring. These guidelines ensure that plans of operation, reclamation plans and reclamation bonds fully address all costs of reclamation and that reclamation is accomplished in a timely manner; ensure that mine operators and owners limit new road construction, decommission unnecessary roads and maintain needed roads consistent with Forest Service policy; require inspections and monitoring on a regular basis consistent with potential severity of mining related impacts; and limit clearing of trees and other vegetation to the minimum necessary for operations (pages 58-59).

Forest Plan Direction

The 1988 Plumas National Forest Land and Resource Management Plan (commonly referred to as the "Forest Plan"), as amended by the 1999 HFQLG final EIS Record of Decision, and as amended by the 2004 SNFPA Final Supplemental EIS Record of Decision, guides the proposed action and alternatives. Forest wide Standards and guidelines for minerals and geology are outlined in the Forest Plan and help move the project area towards desired conditions described in that plan. General direction is to "Encourage mineral and materials development that reasonably protects surface resources, and provides for land reclamation; maintain and update a materials source inventory for Forest uses; recommend withdrawal from mineral entry areas valued for other purposes; protect public safety and Forest resources from slope failure; and prevent loss of groundwater quality and quantity", Chapter 4, Forest Wide Standards and Guidelines (page 4-46 to 4-49).

Effects Analysis Methodology

Specific Assumptions

The project boundary encompasses several areas where Plan of Operations have been submitted and approved but are currently on hold by the owner or operator for a variety of reasons. These plans may be activated at any time. These plans include Golden Wolf #2, Golden Wolf #7, Forman's Jackpot #1, Forman's Gold #2, and Three Golden Stars #4. Analysis of the project area will assume that these plans will be activated during the course of Keddie Ridge Project implementation.

Specific Methodology

In order to understand the contribution of past actions to the cumulative effects of the proposed action and alternatives, this analysis relies on current environmental conditions as a proxy for the impacts of past actions. This is because existing conditions reflect the aggregate impact of all prior human actions and natural events that have affected the environment and might contribute to cumulative effects.

This cumulative effects analysis does not attempt to quantify the effects of past human actions by adding up all prior actions on an action-by-action basis. There are several reasons for not taking this approach. First, a catalog and analysis of all past actions would be impractical to compile and unduly costly to obtain. Current conditions have been impacted by innumerable actions over the last century (and beyond), and trying to isolate the individual actions that continue to have residual impacts would be nearly impossible. Second, providing the details of past actions on an individual basis would not be useful to predict the cumulative effects of the proposed action or alternatives. In fact, focusing on individual actions would be less accurate than looking at existing conditions, because there is limited information on the environmental impacts of individual past actions, and one cannot reasonably identify each and every action over the last century that has contributed to current conditions. Additionally, focusing on the impacts of past human actions risks ignoring the important residual effects of past natural events, which may contribute to cumulative effects just as much as human actions. By looking at current conditions, we are sure to capture all the residual effects of past human actions and natural events, regardless of which particular action or event contributed those effects. Third, public scoping for this project did not identify any public interest or need for detailed information on individual past actions. Finally, the Council on Environmental Quality issued an interpretive memorandum on June 24, 2005 regarding analysis of past actions, which states, "agencies can conduct an adequate cumulative effects analysis by focusing on the current aggregate effects of past actions without delving into the historical details of individual past actions.

Scope of the Analysis

Geographic Analysis Area: The geographic boundary for the Minerals Effects Analysis is the Keddie Ridge Project area. This project area encompasses 103,309 acres on the Mt. Hough Ranger District. The rationale for this boundary is that mining claims do not stop at treatment boundaries and the effects of traffic, heavy equipment and smoke would occur across the project area.

Timeframe of Analysis: In the analysis of the project, current ongoing mining projects and reasonably foreseeable actions were considered. The existing condition encompasses the past history of the area including a long and intensive use of the land for mining purposes. The timeframe that these cumulative effects would impact mining is during the project and for 10 years beyond its completion. During the project there will be disturbance from logging, hand piling and burning.

Analysis Methodology

Mining claim data and claim locations were acquired through the Bureau of Land Management (BLM) LR2000 database [11] and the BLM GeoCommunicator database [12]. Information from these sources was cross referenced with the Keddie Ridge Project map to determine areas of impact. Acreages were taken from project specific GIS data.

Affected Environment

The Keddie Ridge Project area has experienced extensive copper and gold mining over the last century, and some gold mining and copper exploration continues today. There are approximately 168 active mining claims in the project area: most of these are placer claims with a few lode claims. Most claims are worked by small time operators who mine for gold utilizing gold pans and sluice boxes. Historically, many claims have been worked with suction dredges; however, there is currently a moratorium on suction dredging in the state of California. Several operators have larger operations involving trenching and

[11] http://www.blm.gov/lr2000/
[12] http://www.geocommunicator.gov/GeoComm/index.shtm

processing through trommels and power sluices. Some underground mining takes place as well. Exploratory copper mining (core drilling) has occurred in the Moonlight area over the past 10 years. These claims are still active, but are not currently under a Plan of Operations.

The Mt. Hough Ranger District currently administers three active Plans of Operation and four Notices of Intent for active mining operations in the project area. In addition, there are multiple claims for which plans have been submitted and completed, but are on hold by the owner operator. These could be activated at any time.

Historic and current day mining creates deep horizontal adits and vertical mine shafts that dot many locations in the project area. Terrain, ground cover, and a lack of surrounding structures make many of these mine shafts difficult to see, and because the open shafts are not readily visible, they pose a direct hazard to Forest visitors. There are two known abandoned mines in the Keddie Ridge Project area; with many more likely but not yet identified.

Environmental Consequences

Alternatives A (Proposed Action), C, D and E

Direct and Indirect Effects (Alternatives A, C, D and E)

With all action alternatives, the main impacts will be on mining activities at 3 separate claims. These claims include El Rico Mina, Forman’s Jackpot #1 and Forman’s Gold #2. At El Rico Mina, haul routes along National Forest System (NFS) road 26N81 road could directly affect mining operations. This mining operation is directly adjacent to treatment unit #66. Mining is authorized under a Plan of Operations along the shoulders of the road and may be interrupted during periods of haul travel. Smoke may be an additional concern for the mine operators during peak burning periods.

At the Forman’s Jackpot #1 and Forman’s Gold #2 claims, mining operations are planned for areas along the southwest side of NFS road 26N02, between the road and the South Fork of Lights Creek. Exploratory trench work has been authorized under a Plan of Operations. These claims fall within treatment unit #85. Impacts to this mining operation would include shared use of the NFS road and shared use of the surface in areas proposed for mining. Logging trucks, heavy equipment and water trucks will increase the potential hazards encountered by miners and other users of the road systems within the project area. Impacts to mining operations could also occur at Forman’s Ravine claims during periods of underburning. Potential conflicts could be resolved through notification of the operator regarding project timeframes and coordination of project efforts. The placing of signs in treatment areas would also help to reduce conflicts.

Part of the Keddie Ridge Project is to underburn certain areas and pile burn in others. The smoke from burning would have a temporary impact on air quality in the area. Most mining operations take place during the summer months, typically Memorial Day weekend through mid-October. Burning that occurred outside this typical mining season would have less of an impact on claimants.

There are several mining claims in the vicinity of the proposed road construction and road decommissioning.[13] These six claims are located in T27N, R8E, east 1/2 of Section 35. [14] However, these claims may be accessed via NFS road 27N92 and therefore there should be no direct effect on mining due to road decommissioning. Road maintenance and improvements undertaken during the project will benefit mining claimants and improve claim access.

Forest visitors are not at substantial risk from direct contact with herbicides under normal conditions. The Human Health Risk Assessment demonstrates that application of the herbicides Glyphosate and Aminopyralid and the fungicide borax, as proposed by the Keddie Ridge Project, is expected to present a low risk to human health and safety of forest visitors and therefore would not have a direct affect upon mine operators (appendix I).

The indirect effects of all action alternatives within the area boundary would be to reduce fuel loading and improve access to the surface. This would have a beneficial effect for mining claimants as it would thereby improve access to subsurface resources. There would be a beneficial effect of reducing the risk of wildfire and aesthetically cleaning up the stands of trees. Road maintenance would also improve mining access. There may be some indirect effect on mining operators as there would be with any forest visitor due to heavy equipment and haul traffic in the area during the life of the project. There may be some indirect effects on access to future mining claims from road decommissioning but it would be minor and limited.

Herbicide applications would not cause any indirect effects on mine operators. Herbicide applications are expected to present a low risk to human health and safety as demonstrated in the Human Health Risk Assessment (appendix I).

Cumulative Effects (Alternatives A, C, D and E)

In the analysis, cumulative effects of past actions, the action alternatives, current ongoing actions and reasonably foreseeable actions were considered. The existing condition encompasses the past history of the area including mining throughout the project area. Future fuels reduction projects would serve to reduce hazardous fuel conditions that could threaten mining areas, historic structures and equipment. Reasonably foreseeable future projects (identified in appendix F) that would close or fence off abandoned mine shafts would help reduce safety risks to Forest visitors. Overall, there will be no significant cumulative effects from implementation of the action alternatives.

Alternative B – No Action Alternative

Direct and Indirect Effects (Alternative B)

Forest ground cover and fuel loading not addressed by fuels reduction may impact the accessibility of areas for exploratory mining utilizing trenching methods. Many mine operators tend to target areas with minimal understory vegetation when selecting areas for exploratory trenching. Dense stands are more problematic for heavy equipment and an open canopy allows for better access to surface resources. The no action alternative would be less beneficial to miners seeking improved accessibility.

[13] http://www.blm.gov/lr2000/
[14] http://www.geocommunicator.gov/GeoComm/index.shtm

Road access would remain the same under the no action alternative. Roads will deteriorate further without maintenance.

Although there are currently no active mining claims accessed by roads selected for decommissioning under the action alternatives, the no action alternative would allow access to potential new claims in these areas.

Cumulative Effects (Alternative B)

There would be no reduction in available mineral resources or mining opportunities under this alternative because there would be no change in current conditions. However, a large-scale fire could have adverse effects on the miner's environment. Hazardous fuel conditions contributed to the severity of the Moonlight Fire near Antelope Lake. Vegetation in these areas has been slow to return and has created a barren looking landscape. Snags from the fire still pose a safety hazard to miners in the Lights Creek and Indian Creek areas.

Scenic Resources

Introduction

Viewing scenery consistently rates as a popular recreation activity on the Plumas National Forest. Scenic resources contribute indirectly to local quality of life, tourism, and economic vitality. Scenic quality within the Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project) is important to people who enjoy views from the communities in Indian Valley, including Greenville, Crescent Mills, and Taylorsville.

This evaluation applies current National Forest Landscape Management methodology in conjunction with existing *Plumas National Forest Land and Resource Management Plan* (Forest Plan) direction. The Keddie Ridge Project will help achieve Forest Plan direction for scenic resources by perpetuating the area's landscape character (attributes, qualities, and traits that make a landscape identifiable or unique), and conserving its scenic integrity (natural appearance).

Analysis Framework: Forest Plan Direction

Regulatory Framework

The 1988 *Plumas National Forest Land and Resource Management Plan* established goals, policies, and objectives for the management of the forest (USDA 1988, pages 4-3 to 4-11 and 4-13 to 4-20). The following specific Forest Plan goal applies to scenic resources:

- "Allow management activities to dominate the visual landscape of lands committed to intensive timber or other commodity production. Maintain high visual quality on lands committed to other uses or readily apparent from recreation developments, major travel routines, and other high use areas" (USDA 1988, page 4-4).

Visual Quality Objectives

The Visual Quality Objectives (VQOs) contained in the Forest Plan are used to identify and classify scenic resources in the Keddie Ridge Project area.

VQOs were mapped as part of the forest planning process using Agriculture Handbook 462 – Visual Management System, volume 2, chapter 1 (USDA 1974). The VQOs describe different degrees of acceptable alteration of the natural and characteristic landscape. The objectives are considered the measurable standards for the management of the "seen" aspects of the land. Standards and Guidelines outlined in the Forest Plan provide direction for managing land classified under different VQO definitions (USDA 1988). Standards and Guidelines for managing land classified under the four VQOs present within the Keddie Ridge Project area are as follows:

- **Retention** – Provide a natural-appearing landscape where management activities are not visually evident.
- **Partial Retention** – Provide a natural-appearing landscape where management activities remain visually subordinate.
- **Modification** – Allow management activities to dominate the landscape; however, keep visual elements comparable to those of natural occurrences.
- **Maximum Modification (MM)** – Allow management activities to dominate the landscape; however, keep background visual elements comparable to those of natural occurrences.

Methodology for Assessing Impacts on Scenic Resources

Geographic Area Evaluated for Impacts

The geographic area analyzed for effects on scenic resources (the analysis area) is the Keddie Ridge Project area. The analysis area is located west of Canyon Dam, east of Eisenheimer Peak, south of Keddie Peak, and north of the Greenville Wye. The analysis area encompasses two developed recreation sites: Greenville Campground and Round Valley Picnic Area. There are approximately 7 miles of non-motorized system trails within the analysis area. These trails include Peters Creek Trail, Round Valley Interpretive Trail, and Indian Falls Interpretive Trail.

Indicator Measures

Visual Quality Objectives (VQOs) are the indicators analyzed in detail for scenic resources. Aesthetic identity (landscape character) and natural appearance (scenic integrity) are two indicators used to measure scenic quality changes and effects. Landscape character is defined as the attributes, qualities, and traits that make a landscape identifiable or unique, and scenic integrity is considered the natural appearance of a site.

Analysis Methods

The Visual Management System (which includes VQOs) presents a vocabulary for managing scenery and a systematic approach for determining the relative value and importance of scenery and associated recreation in a National Forest. High-quality scenery, especially scenery with naturally appearing landscapes, enhances the lives of local community members and forest visitors. Ecosystems provide the environmental context for this Visual Management System. The system is used in the context of ecosystem management to inventory and analyze scenery in a National Forest, assist in the establishment of overall resource goals and objectives, monitor the scenic resource, and ensure high-quality scenery for future generations.

Duration

The timeframe considered for cumulative effects is based on past and present vegetation management activities dating back to 1980 and past wildfires dating back to 1979 (appendix F). As discussed in the "Forest Vegetation and Fire, Fuels, and Air Quality section of chapter 3, past management activities have contributed to the existing scenic landscape. Future activities were considered (appendix F) in this analysis, but only until the time that Keddie Ridge Project implementation has been completed. Unanticipated future wildfires and other treatments could occur prior to completion of the Keddie Ridge Project, potentially affecting the area's scenic character.

Affected Environment

The landscape in the Keddie Ridge Project area ranges from the flat areas in and around Indian Valley, to moderately and extremely steep slopes. The forests are primarily mixed conifer types, with some pine dominated stands. Red and white fir-dominated forests exist at higher elevations. Valued scenery attributes include the diverse and largely continuous tree canopy of mixed conifer and understory vegetation. Past activities such as mining, grazing, and timber harvesting, fire exclusion, and high-severity wildfires have heavily influenced the existing landscape character of the project area. These past activities have created many areas where dense even-aged stands of trees dominate the landscape. Vegetation is often dense, largely due to historic fire suppression, making for a moderate risk that valued scenery attributes may be lost for decades or centuries through wildfire events.

Scenic resources include views of naturally appearing landscapes such as landforms, vegetation, rock formations, and water features. Scenic resources in the Keddie Ridge Project area are important to forest visitors who may enjoy views anywhere from the floor of Indian Valley to ridges such as Keddie Ridge. Scenic attractiveness is common in many locations in the project area and is used as a measure of the scenic importance of the landscape.

Visual Quality Objectives

Four Visual Quality Objective (VQO) definitions apply to the landscape in the project area: Retention (14,675 acres), Partial Retention (28,225 acres), Modification (38,201acres), and Maximum Modification (1,009 acres).

The Forest Plan describes the types of activities that may occur within Keddie Ridge treatment units:

- **Retention (189 acres in treatment units)** – activities are not to be evident to the casual forest visitor.
- **Partial Retention (2,970 acres in treatment units)** – activities may be evident but must remain subordinate to the characteristic landscape.
- **Modification (2,599 acres in treatment units)** – activities may dominate the characteristic landscape but must, at the same time, use naturally established form, line, color, and texture. Activities should appear as a natural occurrence when viewed in the foreground or middleground.
- **Maximum Modification (35 acres in treatment units)** – activities may dominate the characteristic landscape but should appear as a natural occurrence when viewed as a background.

Sensitive Places, Viewsheds/Viewpoints

Several areas within the analysis area are defined by a VQO of Retention. These areas include a portion of Highway 89 near Indian Falls, a portion of Highway 89 outside of Greenville, an area along Highway 89 at the turnoff from Highway 70, a portion of land in the Arlington Heights area, and land surrounding Round Valley Reservoir within the Round Valley Picnic Area.

The only treatment units proposed on land with a VQO of Retention surround Round Valley Reservoir. The purpose and need for these units (71, 72, 73, 74, 75, 75a, 106 and 107) includes fuel reduction, forest health, and protection/enhancement of habitat for sensitive plant and wildlife species.

Existing Scenic Integrity

Overall, the scenic integrity in the Keddie Ridge Project area meets the VQOs for Maximum Modification, Modification, Retention, and Partial Retention. However, the Moonlight Wheeler Fire of 2007 greatly compromised scenic integrity within the northeastern portion of the analysis area. Many scenic values were lost as approximately 64,960 acres of National Forest System land burned. Many of these acres burned with stand-replacing high severity fire. The charred landscape is visible from many places within the analysis area.

Desired Landscape Character

The desired landscape character for the Keddie Ridge Project area is a slightly more open forest cover, displaying and sustaining an uneven-aged, multistoried, fire-resilient, largely continuous mature tree canopy of mixed conifer and understory vegetation (USDA 1988 pp. 4-95 and 4-105). Dense vegetation in stands classified under Retention and Partial Retention VQOs would be managed to meet the Visual Retention and Visual Partial Retention prescriptions (USDA 1988 pp. 4-95 and 4-105), while reducing the risk that valued scenery attributes may be lost for decades or centuries through wildfire events.

Environmental Consequences

All Action Alternatives (A, C, D, and E)

Direct Effects

Area thinning and group selection would all have a minor beneficial effect on the landscape character. Scenic quality would be improved, and the desired landscape character of a more open and diverse forest would be achieved.

Underburning, group selection, and area thinning activities may have a short-term negligible effect on the scenic integrity of the landscape where burned areas, skid trails, and tree stumps would be visible from forest roads in the analysis area. The desired Visual Quality Objectives (VQOs) for areas in the treatment units may not be met initially after treatments due to project activities, and burning may cause color contrasts between green and brown needles. These effects would diminish over time as VQOs are achieved, and scenic quality would eventually be improved.

Indirect Effects

Fuels treatments in the analysis area would likely have long-term beneficial effects on scenic resources by reducing the risk of a wildfire destroying the existing landscape. Reducing hazardous fuels in the analysis area would likely help ensure that existing scenic landscapes are preserved.

Cumulative Effects

Past activities (grazing, mining, and vegetation management) in the analysis area have all had minor cumulative effects on the landscape character. These past activities have played a large part in creating the landscape that forest visitors identify with. Implementation of area thinning, group selection, and underburning treatments in any of the action alternatives would not drastically change this landscape but would help improve and maintain the desired landscape character that has been shaped by past activities. Future risks of catastrophic fire would be reduced by implementing area thinning and underburning treatments proposed in the action alternatives. Any future vegetation management projects and DFPZ maintenance (appendix F) would slightly benefit the scenic quality of the landscape over the long-term.

Alternative B – No action Alternative

Direct Effects

There would be no direct effects on scenic resources in the analysis area under this alternative because no actions are proposed that would change the landscape character. Scenic quality, however, could be directly affected without area thinning and group selection treatments because lack of treatments would perpetuate existing dense forest canopy and even-aged stand conditions throughout the analysis area.

Indirect Effects

The no action alternative would likely not cause any short-term indirect effects and possibly no indirect effects for years to come. However, without hazardous fuels reduction treatments in the analysis area, the continued risk of a catastrophic fire would increase the potential for long-term adverse effects on the scenic quality of the landscape.

Cumulative Effects

Past activities (vegetation management, grazing, and mining) in the analysis area have cumulatively helped shape the scenic landscape character of the analysis area. The no action alternative would perpetuate adverse cumulative effects on the scenic quality of the analysis area over time because the existing conditions (dense, even-aged stands) would continue, thus increasing the risk of wildfire.

A large-scale fire could have adverse effects on scenic quality for several years. Past hazardous fuel conditions contributed to the severity of the Moonlight and Antelope Complexes of 2007, and the Stream Fire of 2001. The effects from these fires can still be seen from forest roads and campgrounds in and near the analysis area.

Transportation

Analysis Framework: Statute, Regulatory Environment, Forest Plan and Other Direction

Regulatory Framework

The two roads (0.6 miles of National Forest System (NFS) road 28N38A and the 0.4 miles of a non-system road continuation of NFS road 28N38A) in the Keddie Ridge Hazardous Fuels Reduction Project area (Keddie Ridge Project area or project area) that are proposed for decommissioning are causing significant resource impacts. These roads are not needed because other roads are available to provide the necessary access to implement group selection harvests and construct Defensible Fuel Profile Zones (DFPZ) as directed in the *Herger-Feinstein Quincy Library Group Forest Recovery Act* (HFQLG Act) (section 401(b)(1), (d)(1), and (d)(2)) and the Sierra Nevada Forest Plan Amendment (USDA 2003a, 2003b 2004a, 2004b). The Forest Service is directed to reduce impacts on resources caused by transportation by implementing road relocation or improvements as part of the Riparian Management Plan (Appendix R of the HFQLG Final Environmental Impact Statement) as required by the HFQLG Act (sections 401(b)(1), (c)(2)(B), and (d)(4)).

Methodology for Assessing Impacts

Geographic Area Evaluated for Impacts on the Transportation System

The geographic area analyzed for effects on the transportation system (analysis area) is the Keddie Ridge Project area (project area). The analysis area is located west of Canyon Dam, east of Eisenheimer Peak, south of Keddie Peak, and north of the Greenville Wye.

Analysis Methods

The transportation system for the Keddie Ridge Project area was evaluated through a roads analysis. The interdisciplinary process for identifying road system needs and roads with resource damage includes a roads analysis consistent with legal requirements (36 CFR 212 Subpart A—Administration of the Forest Transportation System, 16 U.S.C. 551, 23 U.S.C. 205). The following needs were identified based on that analysis and known access needs for proposed treatments:

- Road reconstruction and maintenance (i.e. brushing) are needed to bring existing classified roads into compliance with current maintenance standards and to provide access to treatment areas. Reconstruction and road maintenance are necessary to reduce erosion and sedimentation and to provide for public safety.
- Road decommissioning is needed to reduce erosion, sedimentation, and soil compaction and to reduce road density and wildlife impacts.
- Out sloping road segments, installing armored rolling dips, and replacing culverts is needed to reduce road induced erosion and improve aquatic organism habitat.
- Temporary road construction is needed to access project units where existing road access is absent.
- Harvest landing construction and reconstruction are needed to facilitate removal of wood products.

Design Criteria

Roads are the largest single human-caused source of sedimentation and habitat degradation within the project area. Improperly constructed or unmaintained roads may restrict aquatic organism passage and transport sediment to streams and riparian areas, thus degrading water quality and aquatic habitat.

To protect watershed resources, the desired conditions for roads that would be retained and improved (through road reconstruction and maintenance) include the following:

- Roads that are needed are maintained and improved to accommodate vehicle traffic. The proposed treatments would provide roads that will ensure safe travel for forest users, and provide a transportation system adequate for all resource management needs.
- Unneeded roads would be eliminated, closed, or obliterated in accordance with the 1988 Forest Plan, as amended, and the Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement (FEIS)(August 2010) and Record of Decision (ROD)(September 2010) (USDA 1988a, b; USDA 2010 a, b).
- Roads that are causing a high level of resource damage would be decommissioned or improved.
- Poorly located roads would be relocated to stable areas.
- Increase habitat connectivity for aquatic species by eliminating roads which degrade habitat.

Affected Environment

Transportation System

One major arterial route accesses the project area, California State Highway 89. Seven collector roads access the project area. The project area is considered to have a fully developed arterial and collector road system.

There are a total of approximately 172 miles of existing National Forest System (NFS) roads in the project area. The system roads are inventoried, mapped, constructed to a specific design level, and categorized into a maintenance schedule. Maintenance levels are identified by road construction use and type. The following miles of roads by road system level categories exist in the Keddie Ridge Project area:

- 27.5 miles of Level 1 roads assigned to intermittent service.
- 118.1 miles of Level 2 roads managed for limited passage of traffic.
- 8.6 miles of Level 3 roads managed for safe travel by a prudent driver in a passenger car.
- 17.6 miles of Level 5 roads where management direction requires the road to provide a high degree of user comfort and convenience at moderate travel speeds.

In addition to the existing classified roads, there are numerous unclassified roads, abandoned roads, and skid trails in the project area. These nonsystem roads, abandoned roads, and skid trails are not part of the annual road maintenance schedule and budget.

The purpose of the NFS road system is to provide suitable conditions for passage of all Forest Service and cooperator emergency vehicles and to meet resource management and public access needs. In addition, needs for the road system include minimized adverse effects on watershed and wildlife resource values. Roads near streams have the greatest probability of intercepting, concentrating, and diverting flows from natural flow paths and should therefore be minimized, where feasible. Road/stream crossings with the potential to fail and divert water should be minimized, where feasible.

Off-Highway Vehicle (OHV) Routes in the Project Area

The Plumas National Forest Motorized Travel Management Project Final Environmental Impact Statement and Record of Decision was completed and signed in fall of 2010. This decision added 234 miles of trails to the existing National Forest Transportation System, creating a total of 4,482 total miles of road and trail access on the Forest. Of that total, 4,118 are available for passenger car use; 4,383 are available for 4-Wheel Drive use; 3,802 are available for unlicensed All Terrain Vehicles (ATV) use; 3,855 are available for unlicensed motorcycle use; and, 4,482 are available for licensed motorcycle use. A subset (165 miles) of the 234 miles will be available immediately while the remainder will need maintenance before they can be used. Implementation of the Plumas National Forest Motorized Travel Management Project will occur when appeals have been resolved and a Motor Vehicle Use Map (MVUM) is published. The MVUM will show which routes are available for use by what types of vehicles and any seasonal restrictions that may apply. Pending any appeal resolution, the MVUM is expected in the spring of 2011. Until then, the current Forest Order regulating use remains in place.

Within the project area, there are 22.2 miles of existing roads and trails open to all vehicles, 12.6 miles of proposed roads and trails open to all vehicles, and 2.6 miles of proposed roads and trails open to vehicles less than 50 inches wide for a total of 37.4 miles of OHV roads and trails in the project area (Table 92). Within project treatment units, there are 5 miles of existing roads and trails open to all vehicles, 2.2 miles of proposed roads and trails open to all vehicles, and 1.3 miles of proposed roads and trails open to vehicles less than 50 inches, for a total of 8.5 miles of OHV roads and trails within treatment units. Haul routes (routes used to transport forest products generated from project implementation) overlap with 13.8 miles of existing OHV roads and trails open to all vehicles. Temporary roads overlap with .8 miles of existing roads and trails open to all vehicles, .6 miles of proposed roads and trails open to all vehicles, and .4 miles of proposed roads and trails open to vehicles less than 50 inches, for a total of 1.8 miles.

Table 92. Miles of OHV Routes Affected within the Project Area and Project Units

Miles of OHV Routes Affected						
	Project Area	Units	TES	Weed Treatment	OHV/Haul Route Overlap	OHV/Temp Roads Overlap
Existing Roads and Trails						
Open to all vehicles	22.2	5.0	0.03	0.9	13.8	0.8
Open to vehicles 50" width or less	0.0	0.0	0.0	0.0	0.0	0.0
Motorcycles only	0.0	0.0	0.0	0.0	0.0	0.0
Proposed Roads and Trails						
Open to all vehicles	12.6	2.2	0.0	0.7	0.0	0.6
Open to vehicles less than 50"	2.6	1.3	0.0	0.5	0.0	0.4
Motorcycles only	0.0	0.0	0.0	0.0	0.0	0
Total	37.4	8.5	0.03	2.1	13.8	1.8

Environmental Consequences

Action Alternatives – A, D and E

Direct Effects

The Keddie Ridge Project proposes road decommissioning of two roads: 0.6 miles of NFS road 28N38A and 0.4 miles of of a non-system road continuation of NFS road 28N38A. These roads are not needed for the long-term transportation system. Decommissioning could include recontouring, removing drainage structures, subsoiling, restoring vegetative cover, restoring hydrological connectivity and/or blocking access. Decommissioning of roads would reduce Equivalent Roaded Acre (ERA) values, thereby lowering cumulative watershed effects and soil compaction. The roads slated for decommissioning are not needed for fire access or resource management and are causing watershed and wildlife impacts.

Roads that are to remain open but are improperly constructed or unmaintained will be improved. Improvements to the road drainage system and road surface prism will be considered for 100 miles of road within the watershed analysis area. Reconstruction would consist of brushing and/or drainage improvements including: out sloping road segments, installing armored rolling dips, or replacing culverts. Rolling dips, which will likely be one of the most commonly prescribed road improvements for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road, depending on the grade/slope of the road. This estimate may vary depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips will be determined by District watershed staff in order to sufficiently disconnect the road drainage system from entering nearby stream channels. Please refer to appendix C for a list of roads where reconstruction will occur.

The road improvements proposed in Alternatives A, D, and E would provide access needed for project units. The proposed improvements would also provide access needed for fire suppression and fuels management to reduce the chance of catastrophic fire through intensive vegetation manipulation at a lower cost because of the improved access. The aforementioned action alternatives would generate traffic from log trucks, chip vans, and support vehicles. Traffic-related safety problems would be mitigated with standard contract requirements. Refer to the Recreation section for information about project effects on recreation, including OHV use.

Indirect Effects

Three temporary license agreements are required for access to treatment units.

Cumulative Effects

A net reduction of approximately 1 mile of system and nonsystem roads in the action alternatives would occur after proposed road decommissioning. Once decommissioned, roads would be available for reforestation and conversion back to a natural landscape.

No Action Alternative – Alternative B and Action Alternative C

Direct Effects

Reconstruction of classified roads would not occur, and impacts on watershed and user safety would continue on roads needing reconstruction. There would be no new direct impact on road surfaces from log haul activity, and there would be no increase in hazards to driver safety from logging traffic. No roads would be decommissioned and these roads would continue to cause resource damage. Normal routine maintenance would occur based on current maintenance levels.

Roads would continue to negatively impact watersheds and public safety because no roads would be reconstructed, decommissioned, or closed.

Indirect Effects

No temporary license agreements would be needed for the normal road maintenance completed in this area.

Cumulative Effects

No reduction in system or nonsystem roads would occur during normal road maintenance completed in this area.

Short-term Uses and Long-term Productivity

NEPA requires consideration of “the relationship between short-term uses of man’s environment and the maintenance and enhancement of long-term productivity” (40 CFR 1502.16). As declared by the Congress, this includes using all practicable means and measures, including financial and technical assistance, in a manner calculated to foster and promote the general welfare, to create and maintain conditions under which man and nature can exist in productive harmony, and fulfill the social, economic, and other requirements of present and future generations of Americans (NEPA Section 101).

Action alternatives would implement mechanical thinning, mastication, hand thinning, and prescribed burning treatments which would remove trees through harvesting or result in tree mortality in the short-term. However, these treatments are designed to retain the largest, most desirable trees in sufficient amounts to meet desired stocking levels and maintain appropriate forest cover as specified by NFMA.

Long-term productivity would far exceed short-term harvest levels and treatments would enhance long-term productivity in terms of forest health, by promoting forest resilience to disturbances such as fire, drought, and insect and disease occurrences.

Action alternatives, primarily through the removal of vegetation and treatment of fire fuels, would directly impact terrestrial habitat for Region 5 Forest Service sensitive wildlife species. Potential short-term effects of entry, use, and alteration of suitable wildlife habitat to achieve project objectives is disclosed in Chapter 3 of this DEIS. Treatments would enhance long-term productivity in terms of forest health, by promoting forest resilience to disturbances such as fire, drought, and insect and disease occurrence. As a result, these treatments over the long-term are expected to increase both the quality and quantity of existing and potential suitable habitat for wildlife species.

Short-term negative impacts to fine organic matter, soil permeability, large woody debris, and channel shading are expected as a result of the proposed activities. Long-term productivity would far exceed these short-term impacts through promoting forest resilience to disturbances such as catastrophic wildfire capable of much greater impacts to the previously mentioned soil and hydrology resources.

In the short-term individual rare plants may be directly impacted from the proposed activities; however over the long-term, these treatments are expected to increase both the quality and quantity of existing and potential habitat for these species.

Over the short-term, the proposed treatments would create disturbed conditions that favor noxious weed establishment and spread. Implementation of the standard management requirements (appendix H) and the weed treatment measures proposed under action alternatives A and D would greatly reduce the risk of noxious weed spread and establishment over the long-term. This risk would not be reduced under action alternatives C and E, primarily due to implementation of ground-disturbing treatment activities with no effective weed treatment measures in place.

The Keddie Ridge Project may affect mining operations in the area in the short-term due to access issues, increased heavy equipment traffic and/or smoke production. No long-term effects to productivity are expected.

Unavoidable Adverse Effects

Action alternatives would implement prescribed burning treatments which would create smoke. Smoke may affect air quality while prescribed fire activities occur; however, prescribed fire activities would be accomplished with an approved smoke management plan to minimize effects to air quality.

Some unavoidable adverse effects may result, including immediate changes in habitat conditions and disturbance/harassment of individual wildlife species, including direct mortality, during project activities. It is assumed in this analysis that all action alternatives would be implemented as proposed, in compliance with all rules and regulations governing land management activities, including the use of Limited Operating Periods. Direct disturbance, including mortality to individual threatened and endangered species addressed in this document, would be highly unlikely due to results of survey efforts for selected species, incorporation of Limited Operating Periods, where appropriate, and implementation of Forest Plan standards and guidelines.

Direct effects on wildlife species could occur as a result of tree removal, mastication, and prescribed burning. These activities have the potential to kill young of the year birds in the nest that cannot fly and species confined to den sites, such as gray squirrels. Increased road use resulting from of project implementation could result in increased road kills of various animals. It is recognized that the proposed project, when implemented during the breeding season (April-September) could directly impact nesting birds. This would affect individual birds. Conservation measures for landbirds, such as snag/down woody retention, use of LOP’s for TES species, avoidance of riparian vegetation, retention of trees greater than thirty inches diameter, which are incorporated into project design, as well as large tracts of forested land not treated with proposed management actions, would alleviate the overall effect on Neotropical migratory bird populations within the analysis area. The Forest Service and the U.S. Fish and Wildlife Service entered into a memorandum of understanding (MOU) in 2008 to strengthen migratory bird conservation. The MOU recognized that direct and indirect actions taken by the Forest Service in the execution of duties and activities, as authorized by Congress, may result in the take of migratory birds, and that short-term negative impacts are balanced by long-term benefits.

The extent of detrimental soil compaction would increase due to mechanical harvest operations. Implementation of standard management requirements would help reduce the amount of detrimental compaction. Treatment activities may lead to increased surface runoff and sedimentation. Implementation of best management practices and standard management requirements would help reduce the amount of detrimental compaction.

There are no foreseeable unavoidable adverse impacts to mining under any of the alternatives for the Keddie Ridge project.

There are no unavoidable Adverse Effects for Heritage Resources.

Irreversible and Irretrievable Commitments of Resources

Irreversible commitments of resources are those that cannot be regained, such as the extinction of a species or the removal of mined ore. Irretrievable commitments are those that are lost for a period of time such as the temporary loss of timber productivity in forested areas that are kept clear for use as a power line rights-of-way or road

Action alternatives would implement mechanical thinning, mastication, hand thinning, and prescribed burning treatments which would 1) remove and/or kill trees, 2) reduce surface fuels and snags and 3) include the removal of forest vegetation for the construction of landings and temporary roads – these effects would be irretrievable commitments of a resource in terms of lost timber productivity and structural attributes. However, these treatments would maintain stocking and appropriate forest cover per NFMA, and tree regeneration, snag and surface fuel recruitment, and rehabilitation of landings and temporary roads would occur over time.

Surface organic matter would be reduced by prescribed fire and underburning, which is an irretrievable effect. Soil porosity would be reduced, also an irretrievable effect, resulting in detrimental compaction. Detrimental compaction is described in the “Hydrology and Soils” section of this chapter under the “Affected Environment—Soils” heading.

Surface fuels, including coarse woody debris, may be removed directly by prescribed underburning and pile burning, an irretrievable effect. Coarse woody debris would be recruited over time via recruitment from existing snags and future tree mortality.

Snags, particularly “soft” or rotten snags, may be removed due to underburning; snags that pose a hazard to firefighters may be felled prior to conducting underburning or pile burning, an irretrievable effect. Snags would be recruited over time from future tree mortality.

Adverse impacts to rare plants will be minimized under all action alternatives through implementation of the design criteria described in appendix H.

If allowed to spread, noxious weed species can have significant adverse impacts to native plants, wildlife species, soil structure, nutrient and fire cycles, and the recreational or aesthetic value of native habitats. While the weed control measures proposed under alternatives A and D would minimize the likelihood of adverse impacts, the lack of effective weed control measures in alternatives C and E would increase the probability of adverse impacts.

There are no irreversible or irretrievable commitments of mineral resources expected under any of the alternatives for the Keddie Ridge project.

There are no irreversible and Irretrievable Commitments of Resources for Heritage Resources.

Legal and Regulatory Compliance

NEPA at 40 CFR 1502.25(a) directs “to the fullest extent possible, agencies shall prepare draft environmental impact statements concurrently with and integrated with …other environmental review laws and executive orders.” The proposed action and alternatives must comply with following:

Principle Environmental Laws

The following laws contain requirements for protection of the environment that apply to the proposed action and alternatives:

Endangered Species Act

Section 7(a)(2) of the Endangered Species Act requires that Federal agencies consult with the United States Fish and Wildlife Service and National Marine Fisheries Service, as appropriate, to ensure that their actions do not jeopardize the continued existence of species listed as threatened or endangered under ESA, or destroy or adversely modify their critical habitat.

A biological assessment was prepared for Federally Proposed, Threatened, or Endangered wildlife and botany species and their critical habitat. Implementation of the project would have no effect on valley elderberry longhorn beetle and California red-legged frog. No Federally Proposed, Threatened, or Endangered wildlife or botany species were located within the Keddie Ridge Project area during past or current surveys.

Clean Water Act

The Forest Service is complying with the provisions of the Clean Water Act as it pertains to the Keddie Ridge Project. Section 208 of the Clean Water Act requires States to prepare nonpoint source pollution plans that are to be certified by the State and approved by the United States Environmental Protection

Agency (EPA). In response to this law, and in coordination with the State of California Water Quality Resources Control Board and EPA, the Forest Service, Region 5, began developing best management practices (BMPs) in 1975 for water quality management planning on National Forest System lands in California. This process identified the need to develop a BMP for addressing the cumulative off-site watershed effects of forest management activities on the benecial use of water.

The Keddie Ridge Project meets this through the incorporation of project design features (DEIS, chapter 2), Scientific Analysis Team (SAT) Guidelines for riparian habitat conservation areas (RHCAs)(USDA 2004b, page 67; USDA 1999a, Appendix L, pages APP L 9-APP L 12; appendix E of this DEIS), soil standards and guidelines (PNF LRMP, pages 4-43 – 4-45); and best management practices, standard management requirements, and monitoring listed in appendix H of the DEIS. Refer to the Hydrology and Soils Environmental Consequences section of this chapter for a discussion of environmental consequences.

Clean Air Act

The Forest Service is complying with provisions of the Clean Air Act as it pertains to the Keddie Ridge Project. All burning implemented under the Keddie Ridge Project would be completed under approved burn and smoke management plans. Burning permits would be acquired from the Northern Sierra Air Quality Management District. The Air Quality Management District would determine dats when burning is allowed. The California Air Resources Board provides daily information on burning conditions. Burning would be implemented in a way to minimize particulate emissions.

National Historic Preservation Act of 1966 as Amended

The Forest Service is complying with the provisions of the National Historic Preservations Act of 1966 as amended as it pertains to the Keddie Ridge Project. Section 106 of the National Historic Preservation Act requires Federal agencies to take into account the effects of their undertakings on historic properties and afford the Advisory Council on Historic Preservation (ACHP) a reasonable opportunity to comment on such undertakings. The Advisory Council on Historic Preservation has defined a Federal undertaking in 36 CFR 800.16(y) as a project, activity, or program funded in whole or in part under the direct or indirect jurisdiction of a Federal agency, including those carried out by or on behalf of a Federal agency; those carried out with Federal financial assistance; those requiring a Federal permit, license or approval; and those subject to State or local regulation administered pursuant to a delegation or approval by a Federal agency.

Coastal Zone Management Act

There are no coastal management zones within the Keddie Ridge Project area or on the Plumas National Forest. The Coastal Zone Management Act does not apply to the Keddie Ridge Project.

National Forest Management Act

The Forest Service is in compliance with the National Forest Management Act as it pertains to the Keddie Ridge Project. Projects occurring on National Forest System lands must meet minimum specific management requirements under 16 U.S.C. 1604 (g)(3). The Keddie Ridge Project meets all applicable guidelines for land management plans according to 16 U.S.C. 1604 (g)(3).

Executive Orders

The following executive orders provide direction to federal agencies that apply to the proposed action and alternatives:

Indian Sacred Sites, Executive Order 13007 of May 24, 1996

Section 1. *Accomodation of Sacred Sites*. (a) In managing Federal lands, each executive branch agency with statutory or administrative responsibility for the management of Federal lands shall, to the extent practicable, permitted by law, and not clearly inconsistent with essential agency functions, (1) accomodate access to and ceremonial use of Indian sacred sites by Indian religious practitioners and (2) avoid adversely affecting the physical integrity of such sacred sites. Where appropriate, agencies shall maintain the confidentiality of sacred sites.

Invasive Species, Executive Order 13112 of February 3, 1999

This document provides an analysis of the effects of the proposed project on noxious weed introduction and spread. The standard management requirements and proposed weed treatment measures were developed to prevent the introduction of invasive species, control the spread of existing infestations, and minimize adverse impacts to National Forest Sysytem lands.

Recreational Fisheries, Executive Order 12962 of June 6, 1995

The effects to fish habitat from the project are expected to be so small that direct effects on fish productivity and the quality of the recreational fishery would be negligible.

Migratory Birds, Executive Order 13186 of January 10, 2001

The environmental analyses of deferral actions are to evaluate the effects of actions and agency plans on migratory birds, with emphasis on species of concern. There is no interagency determination to be made for migratory birds with Federally listed species. Proposed activities and alternatives are not expected to effect migratory birds.

Floodplain Management, Executive Order 11988 of May 24, 1977

These executive orders provide for protection and management of floodplains and wetlands. Compliance with these orders will be assured by incorporating the project riparian management objectives; adhering to the Scientific Analysis Team guidelines, as set forth in the HFQLG FEIS and Record of Decision; and implementing best management practices, standard management requirements, and project design criteria.

Protection of Wetlands, Executive Order 11990 of May 24, 1977

These executive orders provide for protection and management of floodplains and wetlands. Compliance with these orders will be assured by incorporating the project riparian management objectives; adhering to the SAT guidelines, as set forth in the HFQLG FEIS and ROD; and implementation BMPs, standard management requirements, and project design criteria.

Environmental Justice, Executive Order 12898 of February 11, 1994

Although low-income and minority populations live in the vicinity, activities proposed for the Keddie Ridge Project would not discriminate against these groups. Based on the composition of the affected communities and cultural and economic factors, proposed activities would have no disproportionately adverse effects to human health and safety or environmental effects to minorities, low income, or any other segments of the population. Scoping was conducted to elicit comments on the proposed action from all potentially interested and affected individuals and groups without regard to income or minority status.

Use of Off-Road Vehicles, Executive Order 11644, February 8, 1972

The Keddie Ridge Project is in compliance with the Plumas National Forest Public Motorized Travel Management Final Environmental Impact Statement (FEIS)(August 2010) and Record of Decision (ROD) (September 2010).

Special Area Designations

The selected alternative will need to comply with laws, regulations and policies that pertain to the following special areas:

Research Natural Areas

There are no Research Natural Areas within the Keddie Ridge Project area.

Inventoried Roadless Areas

There is a very small portion of PNF LRMP Semi-Primitive land allocation within the Keddie Ridge Project area; however no treatment units overlap with this land allocation. Therefore there will be no impacts to the Semi-Primitive land allocation. There are no Inventoried Roadless Areas within the Keddie Ridge Project area.

Wilderness Areas

There are no Wilderness Areas within the Keddie Ridge Project area.

Wild and Scenic Rivers

A portion of Indian Creek was identified as “eligible” in the PNF LRMP. This portion of Indian Creek is within the Keddie Ridge Project area; however no treatment units overlap with this segment of creek. Therefore, there will be no impacts to the eligible portion of Indian Creek.

Municipal Watersheds (FSM 2540)

Round Valley Reservoir is a municple water supply for Greenville. The activities proposed in the Keddie Ridge Project are expected to be beneficial to Round valey Reservoir. The Keddie Ridge Project meets this through the incorporation of project design features (DEIS, chapter 2), Scientific Analysis Team (SAT) Guidelines for riparian habitat conservation areas (RHCAs)(USDA 2004b, page 67; USDA 1999a, Appendix L, pages APP L 9-APP L 12; appendix E of this DEIS), soil standards and guidelines (PNF LRMP, pages 4-43 – 4-45); and best management practices, standard management requirements, and monitoring listed in appendix H of the DEIS. Refer to the Hydrology and Soils Environmental Consequences section of this chapter for a discussion of environmental consequences.

Chapter 4. Consultation and Coordination

Preparers and Contributors

The Forest Service consulted the following individuals, Federal, State, and local agencies, tribes and non-Forest Service persons during the development of this environmental assessment:

ID Team Members:

Katherine Carpenter – IDT Leader, 4 years, B.S. Wildlife Management
Ryan Tompkins – Silviculturist, 14 years, B.S. Forest Management, M.S. Forestry
Ryan Bauer – Fuels Specialist, 14 years, certificate in Biological Sciences for Federal Land Managers
Chris Collins – Wildlife Biologist, 15 years, B.S. Wildlife Management
Michelle Coppoletta – Botanist, 9 years, B.S. Plant Biology, M.S. Ecology
Liz Long – Planner, 2 years, B.S. Forestry and Natural Resources, B.S. Society and Environment
Kelby Gardiner – Hydrologist, 3 years, B.S. Geosciences (Hydrology)
Cristina Weinberg – Archaeologist, 24 years, B.A. Cultural Anthropology
Elaine Vercruysse – Logging System Specialist, 22 years, B.A. Environmental Sciences
Luke Floch – GIS Specialist, 3 years, B.S. Forestry and Resource Management, M.S. Forestry, certificate in Geographic Information Systems.
Scott Lusk – Range Manager, 20 years, B.S. Wildlife Management, SRM Certified Professional in Rangeland Management #CP00-62, CA PFC Creeks and Communities Riparian Ecologist
Leslie Edlund – Minerals Specialist, 18 years, B.A. Geography, Cal Poly Career Development Program in Forestry
Soai Talbot – Recreation Specialist
Judy Schaber – Recreation Specialist, 26 years, B.S. Environmental Resource Sciences, emphasis on Forestry and Wildlife

Federal, State, and Local Agencies:

U.S. Environmental Protection Agency
Northern Sierra Air Quality Management District
U.S. Fish and Wildlife Service
California Department of Fish and Game
USDA Natural Resource Conservation Service
California Department of Forestry and Fire Protection
Plumas County Road Department
Plumas County Environmental Health Department
Plumas County Board of Supervisors
Plumas-Sierra Counties Department of Agriculture

Central Valley Regional Water Quality Control Board
U.S. Department of Interior

Tribes:

Estom Yumeka Tribe of Enterprise Rancheria
Mechoopda Indian Tribe of Chico Rancheria
Greenville Rancheria
Susanville Indian Rancheria
Concow Maidu Tribe of Mooretown
Tyme Maidu Tribe of Berry Creek Rancheria
Washoe Tribe of California and Nevada

Others:

Plumas County Fire Safe Council
Plumas County Horseman's Association
Sierra Access Coalition
Sierra Forest Legacy
Quincy Library Group
Sierra Pacific Industries
American Forest Resource Council
California Forestry Association
Californians for Alternatives to Toxics
The John Muir Project of Earth Island Institute
Maidu Cultural Development Group
Hank Alrich
Dixie Dursteler-Harrington
Rex Fisher
Frank Stewart
Sierra Pacific Industries
Plumas County Economic Recovery Committee
Plumas Corporation

Distribution of the Environmental Impact Statement

This environmental impact statement has been distributed to individuals who specifically requested a copy of the document. In addition, copies have been sent to federally recognized tribes, State and local governments, and organizations listed above and the following Federal agencies:

- Advisory Council of Historic Preservation, Planning and Review
- USDA Animal and Plant Health Inspection Service PPD/EAD
- Natural Resources Conservation Service

- USDA, National Agricultural Library, Acquisitions and Serials Branch
- National Marine Fisheries Service Habitat Conservationists Division, Southwest Region
- US Army Engineer Division, South Pacific CESPD-CMP
- US Environmental Protection Agency, Office of Federal Activities
- Environmental Protection Agency, Region 9
- US Department of Interior, Office of Environmental Policy and Compliance
- Federal Aviation Administration, Western-Pacific Region
- Federal Highway Administration, California HAD-CA
- US Department of Energy, Office of NEPA Policy and Compliance
- US Coast Guard Environmental Management
- All individuals listed in the public involvement section of chapter 1 of this EIS.

In addition to this list, numerous interested parties will receive notification of the EIS's availability and location on the World Wide Web through written correspondence.

Acronyms

AOC	Area of Concern
APE	Area of Potential Effect
ARCO	*Arabis constancei* (Constance's rock cress)
AT	Area Thinning
ATV	All Terrain Vehicle
BA	Biological Assessment
BAER	Burned Area Emergency Response
BE	Biological Evaluation
BEMA	Bald Eagle Management Area
BMP	Best Management Practice
CASPO	California Spotted Owl Interim Guidelines
CC	Canopy Cover/ Canopy Closure
CEQ	Council on Environmental Quality
CFR	Code of Federal Regulations
CWHR	California Wildlife Habitat Relationships
CYFA	*Cypripedium fasciculatum* (clustered lady's slipper)
DBH	Diameter at Breast Height
DEIS	Draft Environmental Impact Statement
DFPZ	Defensible Fuel Profile Zone
EHR	Erosion Hazard Rating
EIS	Environmental Impact Statement
EPA	Environmental Protection Agency

ERA	Equivalent Roaded Area

Glossary

90th percentile weather conditions — high air temperature, low relative humidity, strong wind conditions and low fuel moisture content levels that historically that are met or exceeded on 10 percent of days during the fire season. It defines potential fire behavior as a result of these conditions: a 90th percentile weather day has the potential for severe wildfire behavior.

Adjuvant — a vegetable oil and silicone-based surfactant used to facilitate and enhance the spreading and penetrating properties of herbicides.

Age class — a distinct aggregation of trees originating from a single natural event or regeneration activity.

Annosum root rot — a conifer disease caused by the fungus *Heterobasidion annosum.* The fungus usually enters through freshly cut stump surfaces. Annosum can cause mortality and butt rot of conifers.

Basal area — the total cross-sectional area of all stems, including the bark, in a given area, measured at breast height (4.5 feet above the ground). Usually given in units of square feet per acre.

Biomass —trees less than 10 inches DBH not used as sawlogs. This material is usually chipped and/or removed from the project area and hauled to the mill to be used for cogeneration of energy or as fiber for wood products.

Board feet — a unit of measure of sawlog volume, equivalent to 12 inches by 12 inches by 1 inch. One thousand board feet is denoted as mbf.

California Wildlife Habitat Relationships (CWHR) — a system developed jointly by Region 5 of the Forest Service and the California Department of Fish and Game that classifies forest stands by dominant species types, tree sizes, and tree densities, and which rates the resulting classes in regard to habitat value for various wildlife species or guilds. The CWHR system has three elements: (1) major tree dominated vegetation associations, (2) tree size, and (3) canopy cover. The major tree dominated CWHR habitats in the Empire Project include red fir, Sierra mixed conifer, ponderosa pine, white fir, montane hardwood, and montane riparian.

Tree size and canopy cover classes are as follows:

Tree Size Classes in CWHR:

1 = Seedling (less than 1 inch DBH)
2 = Sapling (1-6 inches DBH)
3 = Pole (6-11 inches DBH)
4 = Small (11-24 inches DBH)
5 = Medium/Large (greater than 24 inches DBH)
6 = Multilayered (size class 5 over a distinct layer of size class 3 or 4, total canopy greater than 60- percent closure). In this EIS, class 6 is included in class 5.

Canopy Cover Classes in CWHR:

S = Sparse Cover (10-24 percent canopy closure)
P = Poor Cover (25-39 percent canopy closure)
M = Moderate Cover (40-59 percent canopy closure)
D = Dense Cover (greater than 60 percent canopy cover)

Canopy cover — Also referred to as canopy closure. The ground area covered by tree crowns. Canopy cover is expressed as a percent of the area. Values for percent canopy cover can be derived in many ways (From the glossary in the 2004 SNFPA ROD, USFS PSW 2004b).

Cumulative effects — According the Council on Environmental Quality (CEQ) NEPA regulations, “cumulative impact” is the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such actions (40 CFR 1508.7).

Decommission (roads) — closing a road to mechanical use and returning the road to a natural or semi-natural condition. This could include removing stream crossing fills and structures (e.g., culverts or bridges), recontouring to natural topography obliteration (e.g., replacing fill slope material against cut slopes), surface shaping (e.g., constructing in-road water bars), and/or surface scarification.

Defensible Fuel Profile Zones (DFPZ) — a zone approximately 0.25 mile wide accessible to firefighters (usually along roads) in which fuel loads are light enough to cause approaching crown fires to drop to the ground where it may successfully be attacked by ground forces during 90^{th} percentile weather conditions.

Desired conditions — desirable resource conditions for various land allocations or resources, as prescribed in forest plans.

Diameter at breast height (DBH) — the diameter of a tree trunk measured at 4.5 feet above the ground.

Disturbance — a natural event such as fire, flood, or earthquake.

Dripline — the perimeter of the vertical projection of a tree canopy upon the ground.

Duff/duff layer — decaying leaves and branches on the forest floor.

Endemic — in the context of this environmental impact statement, refers to localized pockets within a small area, such as a pocket within a stand or a small stand.

Ephemeral — a watercourse that contains sporadic running water only sporadically, such as during or following storm events. Ephemeral streams have a definable channel and evidence that scour and deposition occur with less-than-annual frequency. Activity buffers are measured from edges of stream channels.

Equivalent Roaded Area — a conceptual unit of measure used to assess ground-disturbing activities. All landscape disturbances are evaluated in comparison to a completely impervious or roaded surface. Road surfaces are considered to represent 100 percent hydrologic disturbance, with maximum rainfall-runoff potential. Other ground-disturbing activities are assigned disturbance coefficients that represent a typical ratio of their hydrologic impact compared to the same roaded area. Disturbance coefficients are assigned based on local coniditons. In a given watershed, disturbances are added together to determine a cumulative equivalent roaded area and compared to the Threshold of Concern.

Erosion Hazard Rating — predicts the potential for sheet, rill, and gully erosion under existing conditions if vegetation and litter are moved.

Fire frequency — the average number of years between fires.

Fireline — a corridor, which has been cleared of organic material to expose mineral soil. Firelines may be constructed by hand or by mechanical equipment (e.g., dozers).

Fire Regime Condition Class — a classification of the amount of departure from the natural fire regime. Assessing Fire Regime and Condition Class can help guide management objectives and set priorities for treatments.

> **Condition Class 1** — fire regimes are within historical range. Risk of losing key ecosystem components to wildfire is low. Species composition and structure are functioning within historical range. Potential wildfire intensities and severity are low to moderate.
>
> **Condition Class 2** — fire regimes are slightly altered from historical range. Risk of losing key ecosystem components to wildfire is moderate. This results in moderate changes in one or more of the following: fire size, fire intensity, and fire severity. In forestland, there is moderate encroachment of shade tolerant tree species. Potential wildfire intensities and severity are moderate to high.
>
> **Condition Class 3** — fire regimes are significantly altered from historical range. Risk of losing key ecosystem components to wildfire is high. This redults in dramatic changes to one or more of the following: fire size, fire intensity, and fire severity. In forestland, there is high encroachment and establishment of shade tolerant tree species. Potential wildfire intensities and severity are moderate to extreme.

Fire type — a description of how a fire burns, such as on the forest floor (surface) or in the tree crowns.

Flame length — the length of flame measured in feet. Increased flame lengths increase resistance to control and likelihood of torching events and crown fires.

Forest Survey Site Class (FSSC) — an index of the productive potential of well-stocked stands. FSSC reflects the mean annual increment of a stand at the point of culmination, and is based on normal yield tables as follows: FSSC 5: 50-84 cubic feet per acre per year; FSSC 6: 20-49 cubic feet per acre per year; FSSC 7: less than 20 cubic feet per acre per year.

Fragmentation/ stand fragmentation — occurs when a large patch of habitat is broken down into many smaller patches of open habitat, resulting in a loss in the amount of quality forested habitat.

Fuel arrangement — how fuels are distributed in the fuel bed.

Fuel bed — the fuels both living and dead that are available to burn.

Fuel loading — the weight of fuel (vegetative matter both living and dead) present at a given site; usually expressed in tons per acre. This value generally refers to the fuel that would be available for consumption by fire.

Group selection — a silvicultural system that involves harvest of small areas of trees (generally less than 2 acres). Implementation results in unven-aged (all-aged) forests consisting of small even-aged (same-aged) groups. Harvest openings must be large enough to allow for sufficient sunlight for regeneration tree seedlings to establish and grow.

Grubbing — removal of vegetation at or below the ground level with hand tools.

Hand line — fire lines created by forest workers using shovels and hand tools to remove organic materials and expose mineral soil. The line width generally ranges between 2 and 3 feet.

Hand piling — piling by hand branches and limbs from tree harvests or thinnings by hand, for burning at a later time.

Hazard Quotient — the ratio of the estimated level of exposure to the reference does or some other index of acceptable exposure.

***Heterobasidion* root disease** — see Annosum root rot.

Home Range Core Areas — these areas are designed to encompass the best available spotted owl habitat, where the most concentrated owl foraging activity is likely to occur, and is in the closest proximity to owl protected activity centers where the most concentrated owl foraging activity is likely to occur. On the Plumas National Forest, each protected activity center is 300 acres and the home range core area is an additional 700 acres, totaling 1,000 acres.

Interdisciplinary Team (ID Team) — the team of Forest Service resource specialists involved in project planning and analysis. The ID Team members for the Keddie Ridge Project are listed in the beginning of chapter 4.

Intermittent — a watercourse with non-permanent flow but having a definable channel and evidence of annual scour and deposition. Activity buffers are measured from edge of stream channel.

Jackpot burn — A burning technique that targets isolated concentrations of heavy fuels.

Ladder (fuel) — shrubs or trees that connect fuels at the forest floor to the tree crowns.

Landings — forested openings, cleared of vegetation, leveled and graded, and used to stockpile sawlogs for eventual loading of load log trucks for haul to a sawmill.

Leave trees — the trees that are purposefully left in a stand that is thinned or harvested.

Mainline — the line used in cable yarding to bring logs to the landing.

Mastication — mechanical grinding of harvest residue or thinning; masticated material is usually left scattered on the harvest site.

Mechanical thinning — the use of tractors, cable systems, or helicopters to remove trees that have been cut by chainsaws; also refers to the use of feller-bunchers (wheeled vehicles with lopping shears or saws that cut and collect trees and carry them to a landing site).

Multilayer — stand with three or more distinct foliage layers (canopies). Trees in the different layers may or may not be in the same age class.

Mycorrhiza/mycorrhizae (pl.) — the mutually beneficial association of a fungus and the roots of a plant, such as a conifer or an orchid, in which the plant's mineral absorption is enhanced and the fungus obtains nutrients.

Natural fire regime — a general classification of the role fire would play across a landscape in the absence of modern human mechanical intervention, but it also includes the influence of aboriginal burning (Agee 1993; Brown 1995).

Operability — the ability to conduct vegetation management operations, which include construction of access roads and log landings, use of cable logging systems, clearing of central skid trails for tractor logging, and removal of trees that pose hazards to forest workers. Trees to be removed for operability would be designated by a Forest Service representative.

Passive crown fire — the movement of fire though groups of trees; it usually does not continue for long periods of time.

Perennial streams — streams that flows continuously. The groundwater table lies above the bed of the stream at all times. Activity buffers are measured from edge of stream channel.

Piling and burning — piling harvest or thinning residues (branches and limbs) and burning them when moisture content has been reduced through evaporation, wildfire hazard is low, and atmospheric conditions are favorable for dispersal of smoke.

Prescribed burning — fire purposefully ignited to achieve a beneficial purpose, such as reducing fuels on the forest floor or fuels generated by logging or thinning forest trees.

Protected Activity Centers (PAC) — areas delineated around nesting sites of nesting pairs of particular wildlife species. Habitat disturbance is minimized or excluded within the delineated area.

Quadratic mean diameter — the upper story diameter of a tree of mean basal area within dominant or codominant positions in the stand. In other words, instead of being an arithmetic average of tree diameters, it is a weighted average based on the basal area of each tree in the upper story within the stand.

Rate of spread — the relative activity of a fire in extending its horizontal dimensions. Expressed as rate of increase of the total perimeter of the fire.

Reconstructed (roads) — reconstruction of an existing road in or adjacent to its current location to improve capacity and/or correct drainage problems. Reconstruction consists of brushing, blading the road surface, improving drainage, and replacing/upgrading culverts where needed.

Regeneration — tree seedlings and saplings that have the potential to develop into mature forest trees.

Release — in the context of this environmental impact statement, giving preferred trees (i.e. old, large pines) more space to grow – to "release" them from crowded conditions.

Residual trees — trees that are left to grow in a stand following treatment or fire.

Riparian Habitat Conservation Area (RHCA) — activity buffers of specified widths along streams and watercourses and around lakes and wetlands that vary according to stream or feature type, as described by the Scientific Analysis Team (SAT) guidelines.

Sanitation — tree removal or modification operations designed to reduce damage caused by forest pests and to prevent their spread.

Seral — relating to a series of ecological communities formed in ecological succession.

Shade intolerant — species (such as ponderosa pine) that require full, open sunlight on the forest floor to establish and grow.

Silviculture — a branch of forestry dealing with the development and care of forests.

Size class — a classification of forest stands based on the average diameter of trees in the stand.

Skidding — dragging a log with a tractor to a landing for loading onto a logging truck.

Skyline — a harvesting system in which a cableway is stretched taut between two points, such as a yarding tower and stump anchor, and used as a track for a block or skyline carriage.

Slash — tree tops and branches left on the ground after logging or accumulating as a result of natural processes.

Snags — a dead standing tree; for wildlife purposes, one that is at least 15 inches in diameter at breast height (DBH) and 20 feet high.

Spotted Owl Habitat Area (SOHA) — areas delineated in land and resource management plans for the purpose of providing nesting and foraging habitat for spotted owls.

Stocking levels — the number of trees per acre in a regeneration site.

Subsoiling — performed after vegetation treatments, wherein mechanized equipment is used to till compacted soil to reduce soil compaction and consequent soil erosion.

Surface fire — a fire that burns surface litter, debris, and small vegetation.

Surfactant — an agent, such as a detergent, that reduces the surface tension of liquids to that the liquid spreads out, rather than collecting in droplets.

Thinning from below — the process of thinning a conifer stand by removing the smallest diameter trees and successively removing larger diameter trees until a canopy cover or basal area retention standard is met for the stand.

Threshold of Concern — the level of watershed disturbance which, if exceeded, could create adverse watershed or water quality effects, in spite of application of best management practices and project design criteria.

Torching — (1) the envelopment in flame of live or dead branches on a standing tree or group of trees; (2) fire burning a single or very small group of trees.

Underburning — a prescribed fire in fuels on the forest floor that is intended to generally remain on the forest floor without consuming significant portions of the forest canopy.

Uneven-aged — a stand of trees of three or more distinct age classes, either inter-mixed or in small groups. Uneven-aged silvicultural systems are a planned sequence of treatments designed to maintain and regenerate a stand with three or more age classes.

White pine blister rust — a disease caused by a fungus that commonly infects sugar pines and causes branch dieback and bole cankers leading to tree mortality if infection is severe enough.

Whole-tree removal — a harvest method where trees are felled at the stump and skidded to the landing for de-limbing, bucking, and processing. Large trees may be bucked in the treatment unit to facilitate removal to the landing and reduce skidding damage to residual trees. Most activity slash would be removed to the landing.

Wildland Urban Interface — the area, or zone, where structures and other human development meet or intermingle with undeveloped wildland or vegetative fuels. It generally extends out for 1.5 miles from the edge of developed private land into the wildland.

Yarding — bringing sawlogs or biomass to a central location for removal from a treatment area.

Appendices

A. **Alternative Development by Unit, Stand Exam Data and Post Treatment Outputs by Unit, and Silvicultural and Noxious Weed Maps with Unit Numbers**

B. **Alternative Maps**

C. **National Forest System Roads Proposed for Reconstruction**

D. **Economic Analysis**

E. **Riparian Management Objectives**

F. **Past, Present, and Reasonably Foreseeable Future Projects**

G. **Public Comments, Response to Public Comments, and Issue Identification**

H. **Standard Management Requirements and Monitoring**

I. **Human Health Risk Assessment**

J. **Project Specific Land Allocation Maps**

Appendix A

Alternative Development by Unit, Stand Exam Data and Post Treatment Outputs by Unit, and Silvicultural and Noxious Weed Maps with Unit Numbers

Introduction

This appendix includes eight tables (Table 1 through Table 8) which display unit specific information for each action alternative. Tables 1, 3, 5, and 7 illustrate tabular data created after developing unit specific information for each alternative. These tables include: unit numbers for each silvicultural treatment unit; unit numbers for those noxious weed treatment units that occur outside of silvicultural unit boundaries; acres; an indicator for units within (“DFPZ”) and outside of (“Non”) DFPZs; prescription; treatment; logging system; purpose and need statement(s) that correspond to each unit; dominant land allocations; dominant California Wildlife Habitat Relationship (CWHR) system size and density classes; presence or absence of noxious weed treatments; visual quality objectives; inclusion of noxious weed treatments; wildlife land allocation(s); presence or absence of threatened, endangered, and Region 5 Forest Service sensitive (TES) plant species; and presence or absence of group selections. This information is then repeated for each unit for each action alternative. Colum headings are not applicable to specific units when the table cells are empty.

Tables 2, 4, 6, and 8 disclose stand exam data and post treatment outputs. These tables include: an indicator for units within (“DFPZ”) and outside of (“Non”) DFPZs; prescriptions; unit numbers, **existing** trees per acre, canopy cover, basal area per acre, quadratic mean diameter, relative density; **residual** quadratic mean diameter; **existing and residual** snags per acres (>15 inches DBH); **average** residual trees per acre, residual basal area per acre, and residual relative density; and **range in** residual trees per acre, residual canopy cover, residual basal area per acre, and relative density. This information is then repeated for each unit for each action alternative.

Figure 1, at the end of this appendix, includes silvicultural treatment units with unit numbers, and Figure 2 displays noxious weed units with unit numbers. These are the only figures that contain unit numbers.

Appendix B, the following appendix, includes alternative specific silvicultural and noxious weed treatment maps, and silvicultural and noxious weed prescription code tables. Appendices A and B should be used together to relate tabular (appendix A) and spatial data (appendix B) for each unit.

Specific Methodology

Plumas National Forest Geographic Information System (GIS) corporate data was used to create Tables 1, 3, 5, and 7 below. The Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project) Interdisciplinary Team (IDT) worked synergistically to review the GIS data, scoping comments submitted by interested parties, and Forest Plan information, as amended, and created these unit specific tables.

Common stand exam data and Forest Vegetation Simulator (FVS) modeling were used to create Tables 2, 4, 6, and 8 below. Proposed treatments and corresponding prescriptions for each alternative were modeled to characterize existing conditions and average ranges in post-treatment stand conditions.

Table 1. Alternative A Development by Unit

Unit #	Acres	DFPZ	Rx	Treatment	Logging System	Purpose & Need	Land Allocation	CWHR	Weed Treatments	VQO	Wildlife	TES plants	GS

Figure 1 Silvicultural Treatment Units with Unit Numbers

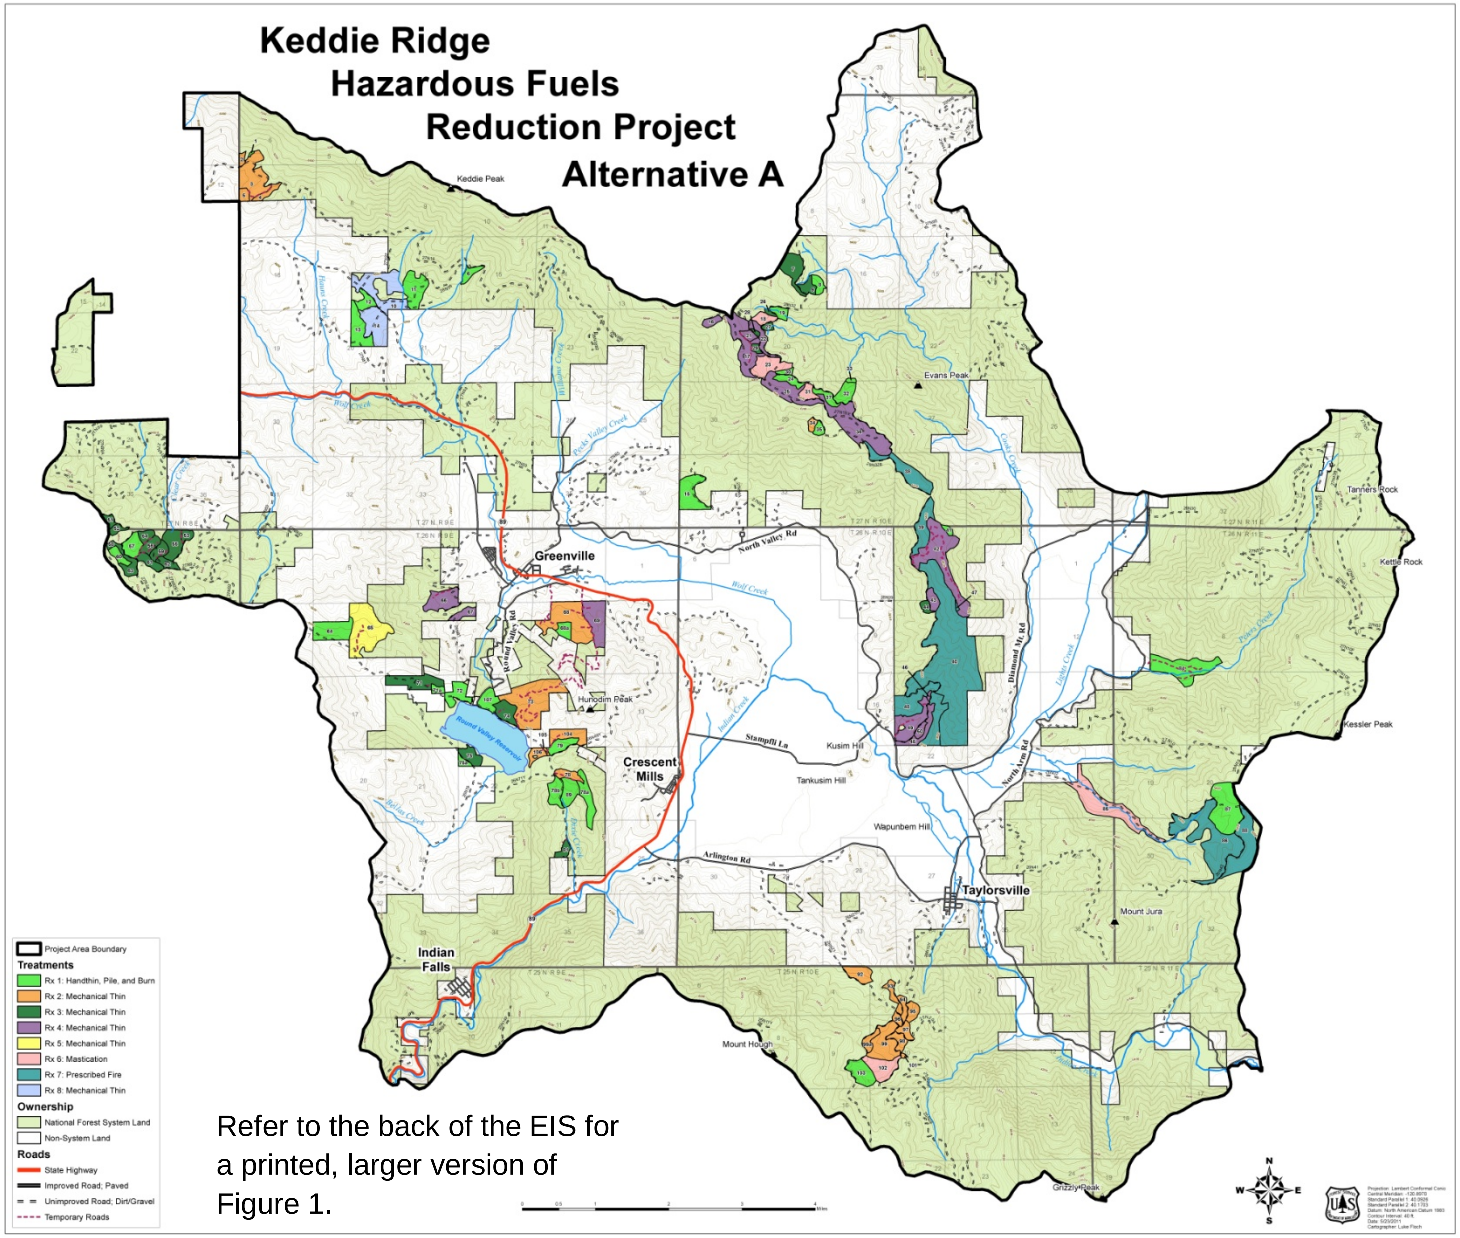

Figure 2 Noxious Weed Treatment Units with Unit Numbers

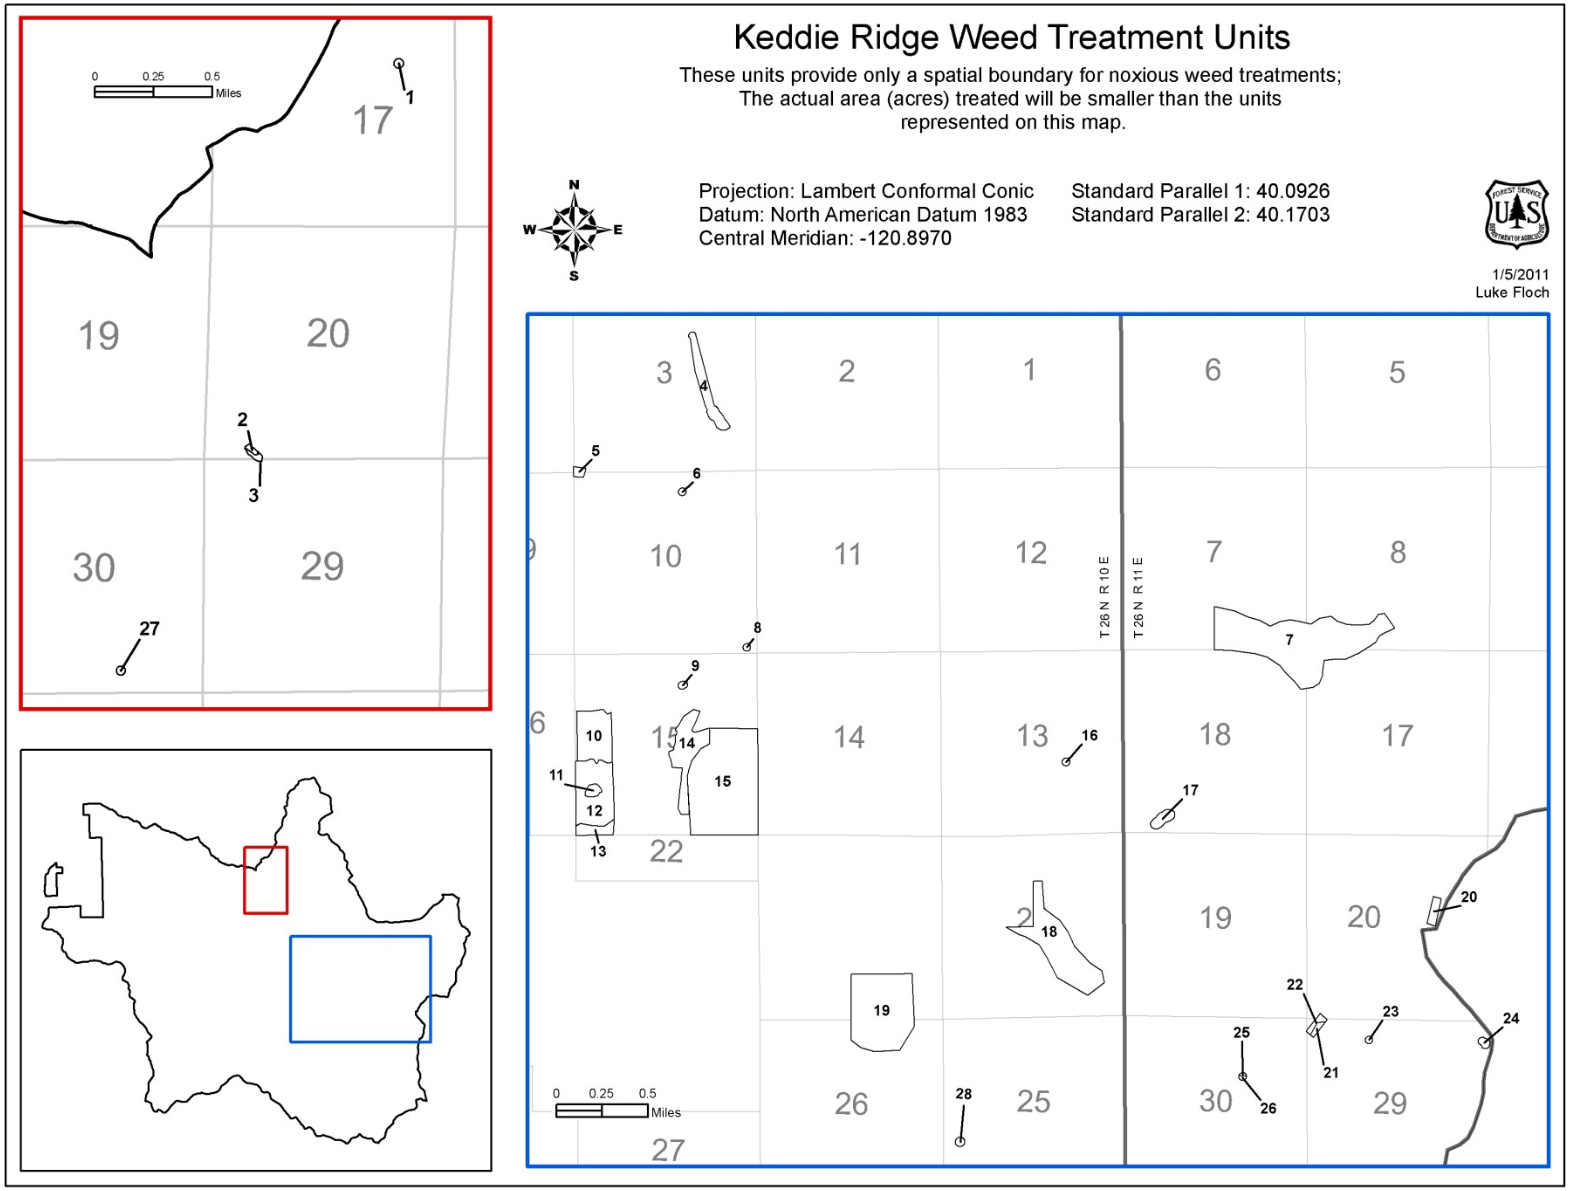

Appendix B

Alternative Maps

This appendix includes alternative specific treatment and noxious weed maps (Figure 1 through Figure 6). This appendix can be used in conjunction with appendix A to compare tabular data (appendix A) and spatial data (appendix B) for each unit within each alternative.

The first four maps (Figure 1 through Figure 4) are silvicultural treatment maps illustrating unit specific prescriptions for each alternative; township, range, and sections; ownership; and major roads, communities, bodies of water, and creeks. Some or all prescriptions change for each unit within each alternative; however, the footprint of the units does not change.

The last two maps (Figure 5 and Figure 6) focus on noxious weed treatment locations. These maps zoom into areas where there are noxious weed treatments. Most of the noxious weed treatments are less than one tenth of an acre and were difficult to see on the silvicultural maps. These weed treatment maps also include township, range, and sections; ownership; and major roads and creeks. Weed treatments are not proposed under alterative C (non-commercial funding alternative); however, implementing fuels treatments would directly benefit noxious weeds under this alternative.

Silvicultural and noxious weed prescription code tables are located at the end of all six maps (Table 1 and Table 2). The prescription code table clarifies which alternative the prescription applies to, the prescription code, and a general description explaining what the prescription is.

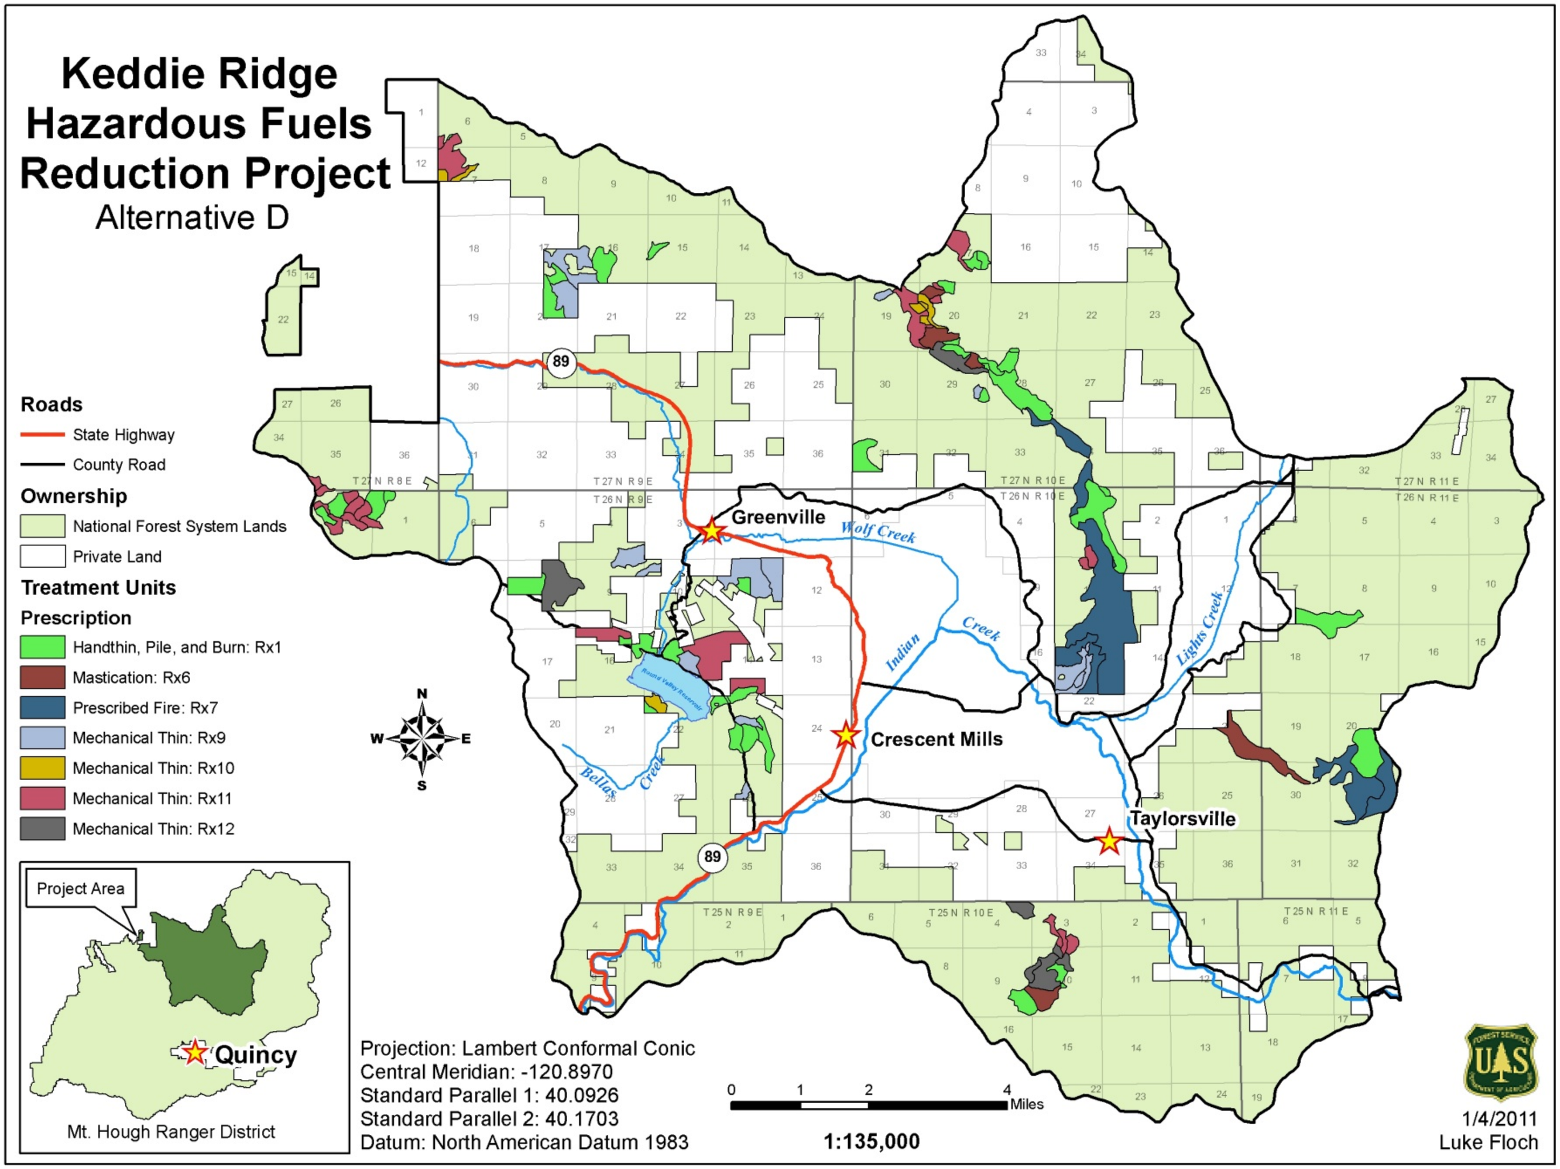

Figure 4 Alternative E Treatment Unit Map with Silvicultural Prescriptions

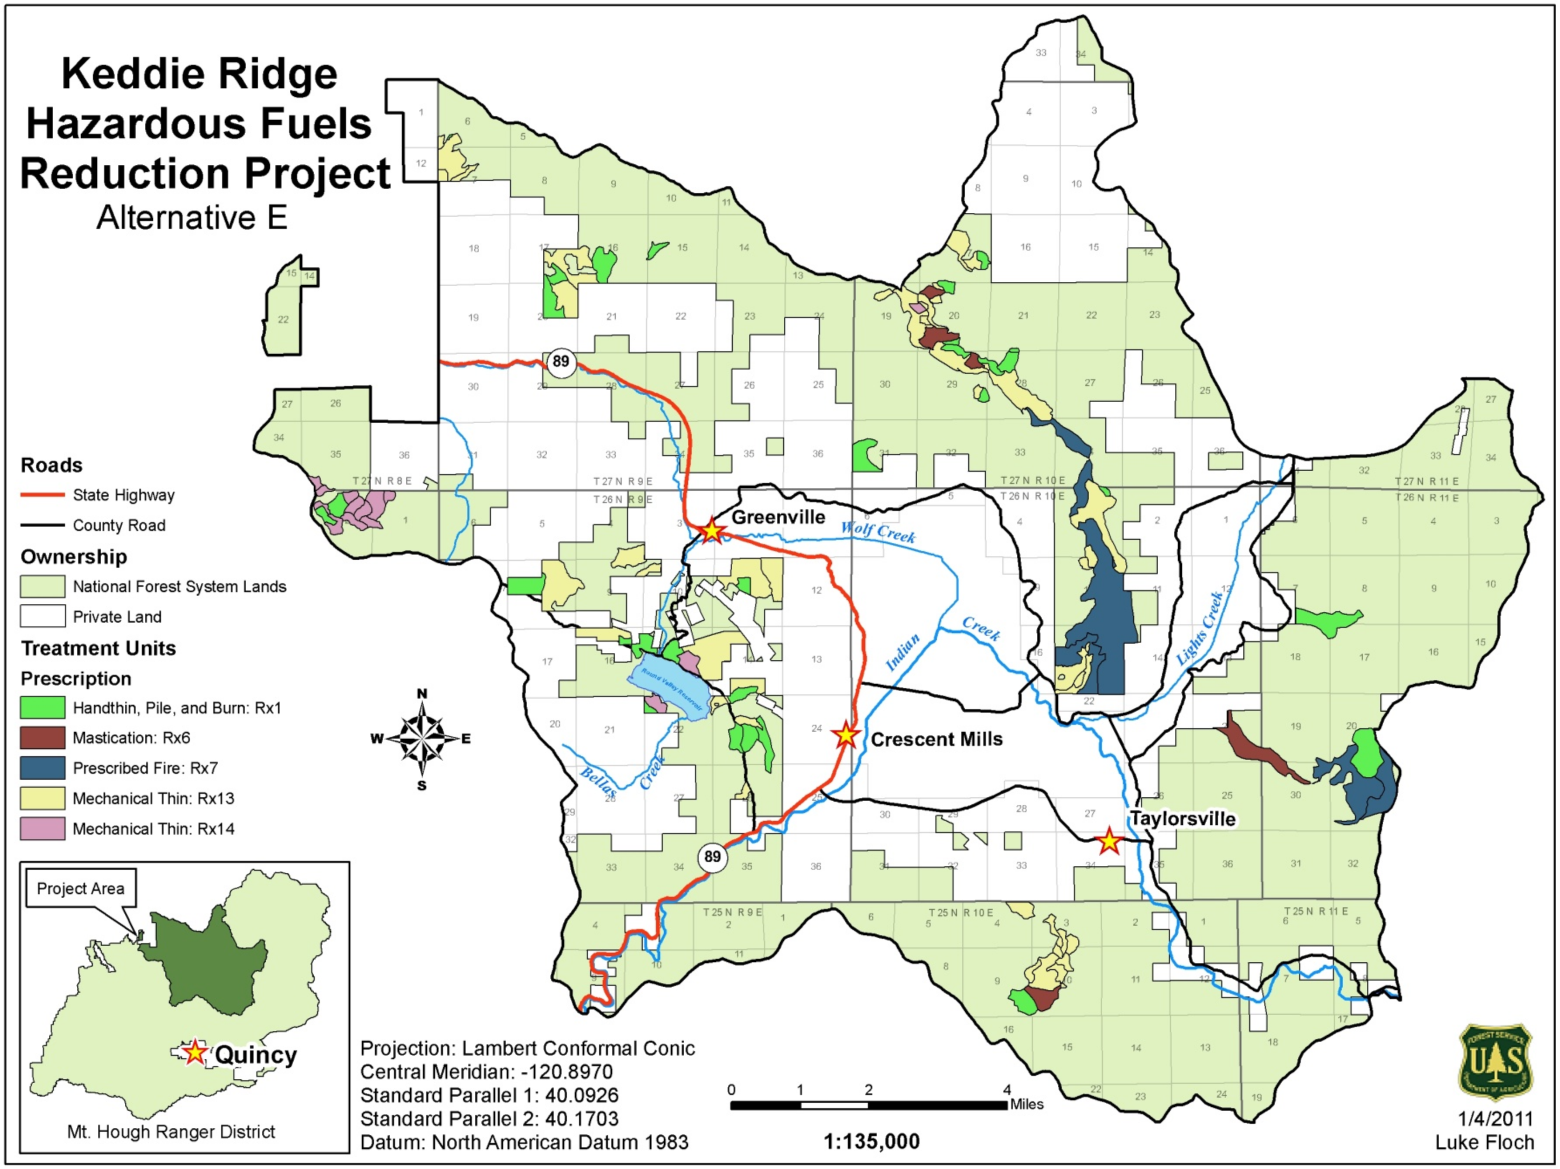

Figure 5 Alternatives A and D Treatment Unit Map with Noxious Weed Prescriptions

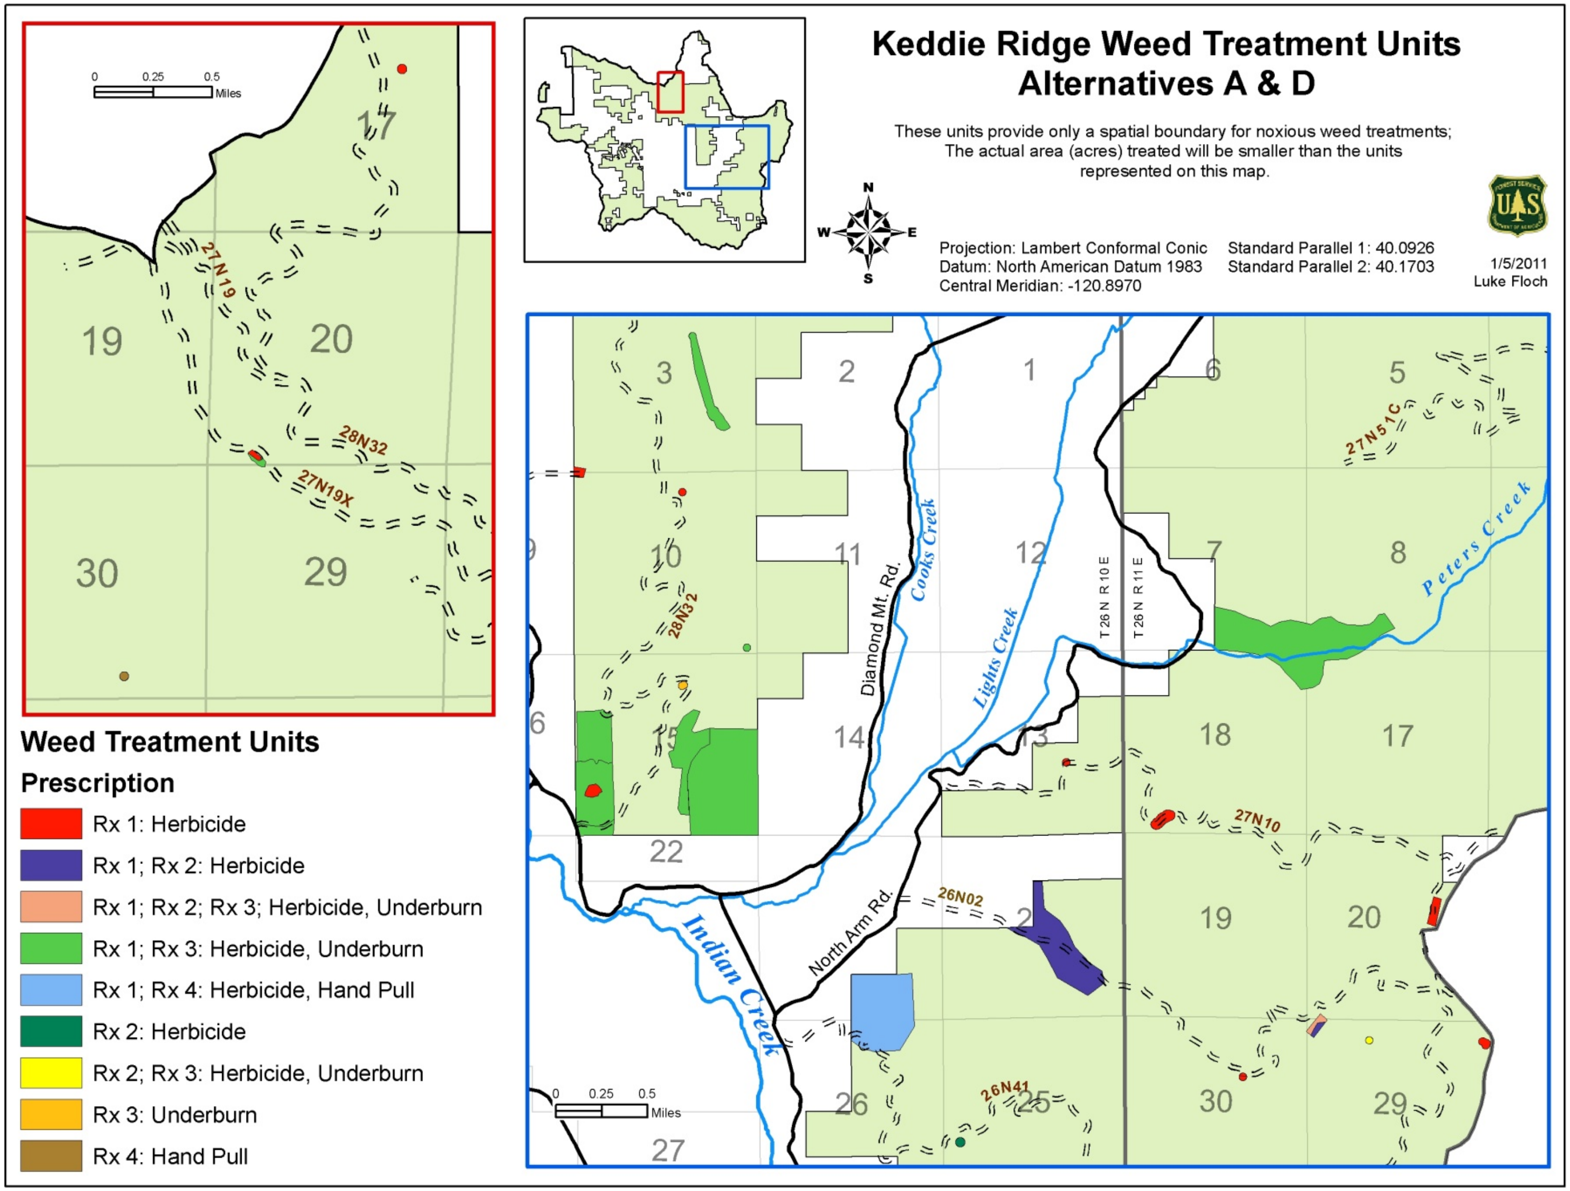

Figure 6 Alternatives C and E Treatment Unit Map with Noxious Weed Prescriptions

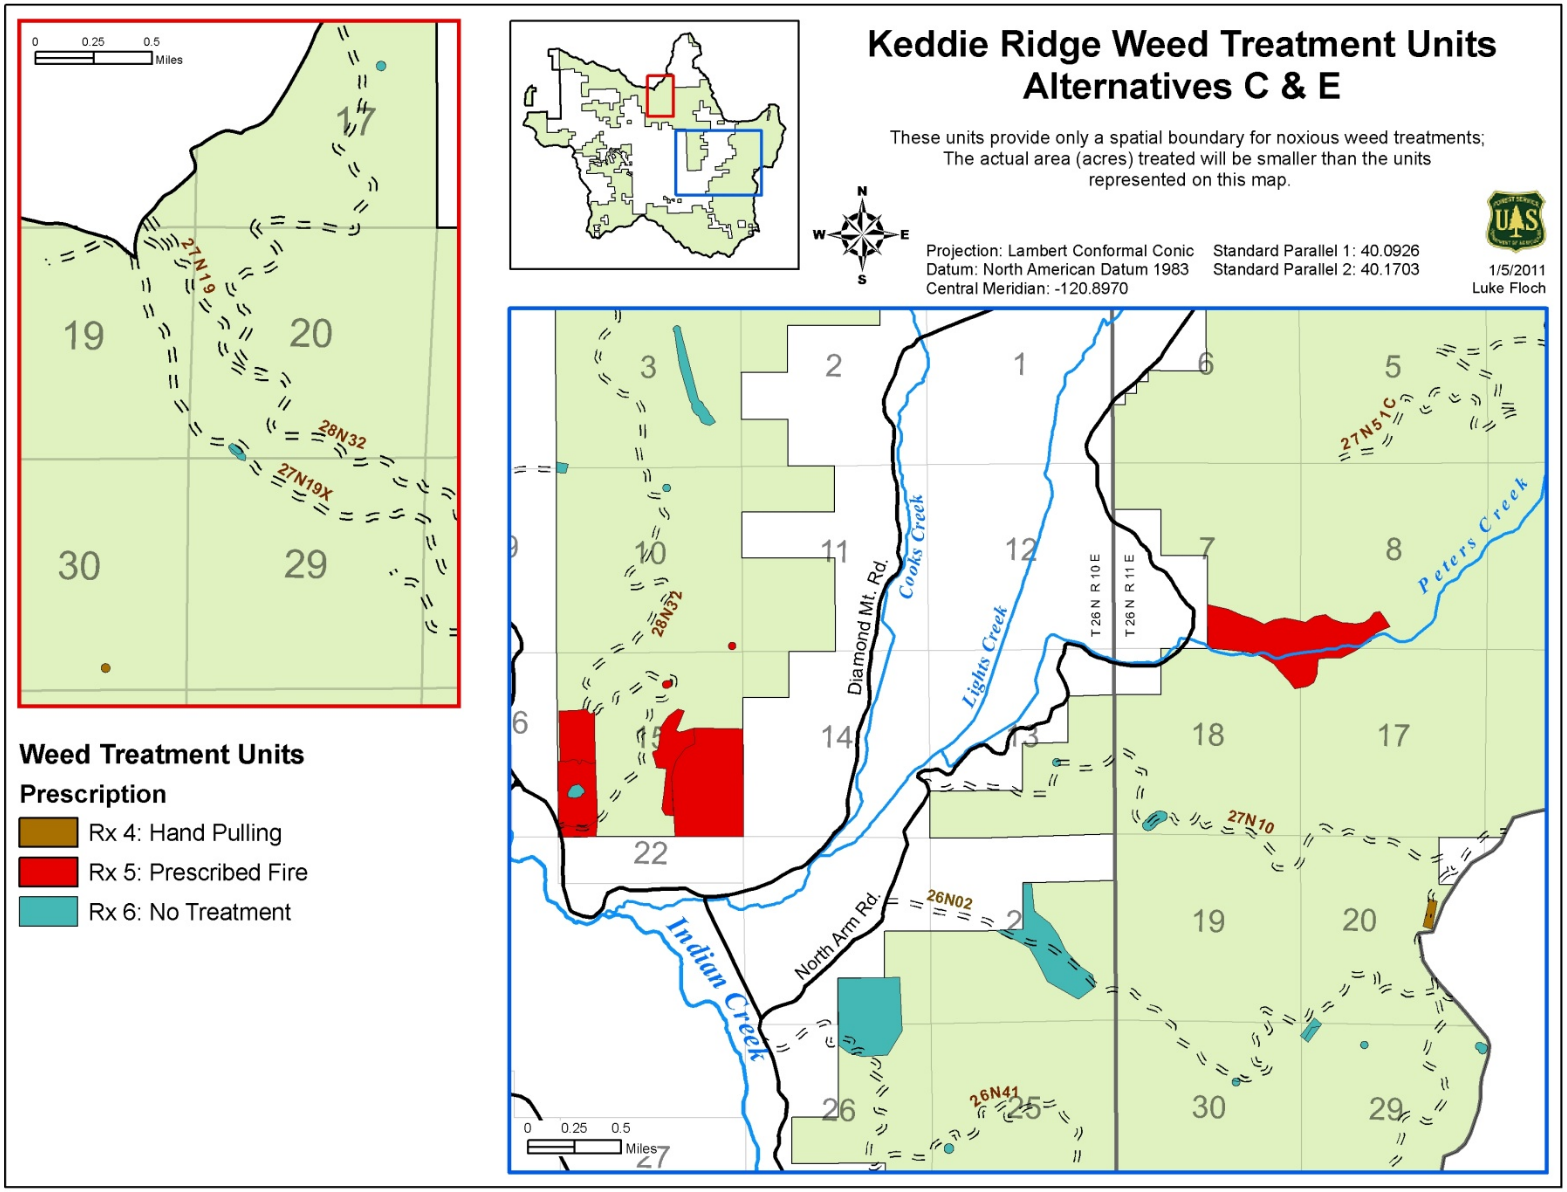

Table 1. Silvicultural Prescription Codes

Alternative	Prescription (Rx)	General Description
A, C, D, & E	**Rx 1**	Hand thin, pile, and burn trees less than 8 inches DBH and underburn.
A	**Rx 2**	Mechanical Thin to 30-40 percent canopy closure (CC), retain all live trees greater than or equal to 30 inches DBH; except in CWHR 5M/5D, thin to 40-50 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in RHCAs thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn.
A	**Rx 3**	Mechanical Thin to 30-40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; except in CWHR 4M/4D, thin to 40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in CWHR 5M/5D thin to 40-50 percent CC, generally retain live trees greater than or equal to 24 inches DBH; in RHCAs, thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn.
A	**Rx 4**	Mechanical Thin to 30-40 percent CC, generally retain live trees greater than or equal to 24 inches DBH; except in CWHR 5M/5D thin to 40-50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; in RHCAs thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn.
A	**Rx 5**	Mechanical Thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches and underburn.
A, C, D, & E	**Rx 6**	Masticate brush and trees less than 10 inches DBH to 25-30 foot spacing and retain all hardwoods greater than 3 inches DBH.
A, C, D, & E	**Rx 7**	Low to moderate intensity prescribed underburn.
A	**Rx 8**	Mechanical Thin to 30-50 percent CC, generally retain live trees greater than or equal to 12 inches DBH, and underburn.
C	**Rx 8**	Mechanical Thin to 30-50 percent CC, retain live trees greater than or equal to 12 inches DBH, in RHCAs, thin to 50 percent CC retain live trees greater than or equal to 12 inches DBH; and underburn. Spring underburn in areas infested with noxious weeds.
D	**Rx 9**	Mechanical Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH, and leave 15 percent of the stand untreated; and underburn.
D	**Rx 10**	Mechanical Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH, and leave 25 percent of the stand untreated; and underburn.
D	**Rx 11**	Mechanical Thin to 50 percent CC, retain all live trees greater than or equal to 20 inches DBH; except in CWHR 5M/5D thin to 50 percent CC retain all live trees greater than or equal to 12 inches DBH, and leave 25 percent of the stand untreated; and underburn.
D	**Rx 12**	Mechanical Thin to minimum 50 percent CC while only reducing the CC less than 10 percent, retain all live trees greater than or equal to 12 inches DBH, and leave 25 percent of the stand untreated; and underburn.
E	**Rx 13**	Mechanical Thin to 30-40 percent CC, retain all live trees greater than or equal to 30 inches DBH; except in CWHR 5M/5D, thin to 40 percent CC, retain all live trees greater than or equal to 30 inches DBH; in RHCAs, thin to 50 percent CC, generally retain live trees greater than or equal to 20 inches DBH; and underburn.
E	**Rx 14**	Mechanical Thin to 40-50 percent CC, retain all live trees greater than or equal to 30 inches DBH; except in RHCAs thin to 50 percent CC, generally live retain trees greater than or equal to 20 inches DBH; and underburn.

Table 2. Noxious Weed Prescription Codes

Alternative	Prescription (Rx)	General Description
A & D	**NW Rx 1**	Apply the herbicide aminopyralid to noxious weed infestations that are greater than 15 feet from the water's edge. Utilize a backpack sprayer for selective application and apply at rates between 0.05 and 0.11 acid equivalent (a.e.) pounds per acre (lbs/acre).
A & D	**NW Rx 2**	Apply the herbicide glyphosate to noxious weed infestations that are (a) between 0-15 feet from the water's edge or (b) within sites dominated by hoary cress. Utilize a wick applicator (in riparian areas) or a backpack sprayer for selective application and apply at rates between 1 and 3 acid equivalent (a.e.) pounds per acre (lbs/acre).
A, B, C, & D	**NW Rx 3**	Implement prescribed fire treatments in the spring and early summer. If necessary, utilze flaming with a propane torch to control weed infestations in areas that are a high risk for spread (i.e. on roads or landings).
A, B, C, & D	**NW Rx 4**	Implement manual control methods such as hand pulling, digging, cutting (i.e. with a weed whacker), or covering. Use manual methods to treat small infestations (i.e. less than 50 plants) and as a follow-up method to herbicide or prescribed fire treatments.

Appendix C

National Forest System Roads Proposed for Improvements

This appendix includes a list of National Forest System (NFS) roads and a few segments of Plumas County roads that are proposed for improvement activities under alternatives A, D, and E.

NFS roads that are to remain open but those that are improperly constructed or unmaintained will be improved. Treatments range from light brushing with no drainage improvements to heavy brushing and large drainage improvements. Drainage improvements may include: outsloping road segments, installing armored rolling dips, or replacing culverts. Improvements to the road drainage system and road surface prism will be considered for 100 miles of road within the watershed analysis area. Rolling dips, which will likely be the most commonly prescribed road improvement for the Keddie Ridge Project, are generally installed at a frequency of 1-4 dips per mile of road. This estimate will vary depending on the existing condition of the road drainage system and the number of stream crossings present. Each dip would be approximately 15 feet long and as wide as the existing road surface. Placement of dips will be determined by district watershed staff in order to sufficiently disconnect the road's drainage system from surrounding stream channels. Refer to Figure 1 for a visual display of National Forest System and Plumas County roads proposed for improvement activities.

Appendix D

Economic Analysis

This appendix includes an economic analysis for each action alternative (A, C, D, and E). Each table breaks across two pages. This appendix relates to the information, data, effects, and conclusions presented in the Economic and Social Environment section of the Keddie Ridge Hazardous Fuels Reduction Project Environmental Impact Statement.

Table 1. Alternative A Economic Analysis

Timber values based on average value of three class sizes (Board of Equalization, based on draft report for timber values for 7/10 thru 12/10). Assumptions: *Harvest Value Schedules, CA State Board of Equalization, Table 4, Area 7, Tractor, 23"-29.9"dbh; **Harvest Value Schedules, CA State Board of Equalization, Misc. Harvest Values, Small Sawlogs, 14"-22.9" dbh; ***Timber Values for 10"-13.9" are $25.00/mbf. Deduction if average volume per acre under 5mbf/ac -$25, under 2mbf/ac -$50. Skyline Yarding $70/mbf with biomass removal and $120/mbf with biomass removal for under 5mbf/acre. Cost/ac for unit size increases 0% for 400 ac to 20% for 5 ac. Cost/ac for contract length decreases 10% every year after one year. Cost/ac for months of operation decreases 10% for 10 months or more and increases 10% for 4 months or less.
Based on historical relationships between employment and harvest in California during the 1980's, each million board feet harvested supports 6.5 year-around jobs (1 in logging, 4 in sawmill, and 1.5 in US Forest Service employment). In regional economic models of employment for California and the Pacific Northwest, and estimate of one indirect or induced job for every direct timber job is added. Indirect jobs result from the employment created by the local purchase of materials for the sawmill, local expenditures by workers, and the demand for local government employees. Each million board feet harvested supports a total of 13 jobs that are timber related. The restoration work would support additional direct and indirect employment. There are approximately 1.4 indirect jobs for every full time field job. All jobs are equivalent to year-around employment. Total employee-related income is calculated by assuming an annual wage of $36,000 per full time job. This estimate is based on an average per capita income for Plumas County of $36,000 based on data in the California Statistical abstract. Lippke B. and L. Mason, 2005 "Implications of Working Forest Impacts on Jobs and Local Economy."

Timber values based on average value of three class sizes (Board of Equalization, based on draft report for timber values for 7/10 thru 12/10). Assumptions: *Harvest Value Schedules, CA State Board of Equalization, Table 4, Area 7, Tractor, 23"-29.9"dbh; **Harvest Value Schedules, CA State Board of Equalization, Misc. Harvest Values, Small Sawlogs, 14"-22.9" dbh; ***Timber Values for 10"-13.9" are $25.00/mbf. Deduction if average volume per acre under 5mbf/ac -$25, under 2mbf/ac -$50. Skyline Yarding $70/mbf with biomass removal and $120/mbf with biomass removal for under 5mbf/acre. Cost/ac for unit size increases 0% for 400 ac to 20% for 5 ac. Cost/ac for contract length decreases 10% every year after one year. Cost/ac for months of operation decreases 10% for 10 months or more and increases 10% for 4 months or less.

Based on historical relationships between employment and harvest in California during the 1980's, each million board feet harvested supports 6.5 year-around jobs (1 in logging, 4 in sawmill, and 1.5 in US Forest Service employment). In regional economic models of employment for California and the Pacific Northwest, and estimate of one indirect or induced job for every direct timber job is added. Indirect jobs result from the employment created by the local purchase of materials for the sawmill, local expenditures by workers, and the demand for local government employees. Each million board feet harvested supports a total of 13 jobs that are timber related. The restoration work would support additional direct and indirect employment. There are approximately 1.4 indirect jobs for every full time field job. All jobs are equivalent to year-around employment. Total employee-related income is calculated by assuming an annual wage of $36,000 per full time job. This estimate is based on an average per capita income for Plumas County of $36,000 based on data in the California Statistical abstract. Lippke B. and L. Mason, 2005 "Implications of Working Forest Impacts on Jobs and Local Economy."

Appendix E

Riparian Management Objectives

Riparian Management Objectives (RMOs)

Riparian and aquatic ecosystems on the PNF are managed to achieve specific riparian management objectives (RMOs) as presented in the Scientific Assessment Team (SAT) Guidelines (USDA 1999a, 1999b, appendix L). Each of the 10 RMOs is listed below followed by a discussion that includes current conditions, project design features, and standard management requirements that achieve those objectives. In general, the Herger-Feinstein Quincy Library Group Forest Recovery Act Environmental Impact Statement (HFQLG EIS) guidelines prohibit activities within the riparian habitat conservation areas (RHCAs) unless they are specifically designed to improve the structure and function of the RHCA and benefit fish habitat. The RMOs that specifically relate to hydrology and apply to the construction of the DFPZ and operations within RHCAs are presented below.

Under all action alternatives, treatments are proposed within RHCAs. In the discussion that follows, most references to treatment within RHCAs are specifically limited to those treatment areas. No RHCA treatment would occur under the no-action alternative.

The objective of the RHCA treatment within fuel reduction units is to reduce the potential for adverse impacts from high intensity wildfire. Historically, fire has been an integral disturbance agent in riparian systems (Dwire and Kauffman 2003). However, fire suppression has reduced the influence of fire, resulting in fuel accumulation and increased likelihood of large, severe wildfires (Taylor and Skinner 1998). RHCA treatments would provide a safer and more effective fire suppression environment, improve forest health, and provide for a more sustainable vegetation condition consistent with protecting and maintaining riparian habitat values.

Field surveys were conducted to verify the existence and condition of the streams and sensitive areas within units that would be mechanically treated. All RHCA treatments are designed to minimize erosion from soil disturbance, and to protect and maintain the riparian vegetation that provides bank stabilization and habitat for wildlife, fish, and other aquatic species. The ten RMOs for the Keddie Ridge Project are discussed below.

1. **Maintain or restore water quality to a degree that provides for stable and productive riparian and aquatic ecosystems. Water quality parameters that apply to these ecosystems include timing and character of temperature, sediment, and nutrients.**

In addition to reducing the risk of high-intensity fires, thinning RHCAs will allow the ecosystem within this corridor to return to a more productive historic condition. Competition between codominant and dominant trees will decrease and growth rates will increase while mortality rates decline. Over time, the crowns of larger more fire resistant trees will fill in, increasing the necessary shade for temperature regulation. Where available, canopy cover will be maintained at 50 percent on average, however this may range between 60 percent along fish bearing streams and 40 percent for non-fish bearing streams.

Proposed thinning, which will occur throughout most RHCAs within the Keddie Ridge Project area, would encourage forest growth and consequently hasten the development of larger trees and the subsequent recruitment of large woody debris to stream channels. Large woody debris is generally scarce throughout the RHCAs due to a shortage of old growth vegetation.

No change is expected in dissolved oxygen levels as they relate to treatments, since any newly created slash would be removed from stream courses within 48 hours after deposition. Thinning RHCAs adjacent to low velocity streams may actually improve oxygen levels by decreasing nutrient overloading from materials decaying in place. Most of the streams within the Keddie Ridge project are low to moderate velocity. In streams, the consumption of organic matter by bacteria requires oxygen. The amount of oxygen required for bacterial decomposition is the biochemical oxygen demand (BOD), a commonly used measure of water quality. When consumption by bacteria is high, oxygen levels in the water are reduced. Low oxygen levels can stress fish and other aquatic organisms.

Where RHCAs would be mechanically treated, ground based equipment would only be used on slopes less than or equal to 25 percent. RHCAs within sensitive areas (e.g., springs, seeps, and wetlands) could be entered with ground-based equipment 25 feet from the edge of the riparian area or wet perimeter of the soil, whichever is greatest. On slopes less than 15 percent, all mechanical equipment would be excluded from within 100 feet (horizontal) of fish bearing streams, 50 feet of perennial and intermittent streams, and 25 feet of ephemeral streams. On slopes between 15 and 25 percent, all mechanical equipment would be excluded from within 150 feet of fish bearing streams, 100 feet of perennial and intermittent streams, and 50 feet of ephemeral streams. In addition, skid trails will be located at angles to stream channels that minimize erosion into the channel, and skidders will only be allowed to back in to the outer RHCA on these skid trails. The mechanical exclusion zones would serve as effective filters and absorptive zones for potential sediment originating from upslope treatment areas. Removal of vegetation within these equipment exclusion zones would be allowed on a site-by-site basis to protect the sensitive attributes associated with the riparian area.

No ignition of prescribed fire would occur within 50 horizontal feet of all streams; however, backing fire would be allowed into these areas. Based on BMP evaluations completed on the Plumas National Forest over the last three years, short-term sediment delivery to streams after prescribed burning has not occurred (USDA 2007, 2008, 2009). Scorched conifers often drop needles following low or moderate severity fires. This needle cast provides ground cover that can help reduce rill and interrill erosion and sediment delivery (Pannkuk and Robichaud 2003). Additionally, the greater long-term benefit of treating these RHCAs is the potential protection from stand-replacing wildfire.

2. Maintain or restore the stream channel integrity, channel processes, and sediment regime under which the riparian and aquatic ecosystems developed. Elements of the sediment regime include the timing, volume, and character of sediment input and transport.

In addition to reducing the risk for high-intensity fires, thinning of the RHCA will allow the ecosystem within this corridor to return to a more stable historic condition. Historically, woody debris was a combination of large and intermediate logs. Debris jams; especially log-jams of small material will alter the natural sediment regime. Small material decays at a faster rate; entrainment of sediments is short term as decaying logs fail. During peak events small material cannot hold sediment in place. Released sediment will affect timing, volume and character of the input. End cutting and scouring within the channel caused by heavy loading of dead and downed material will influence the timing, volume, and character of sediment being transported through the system.

Equipment induced ground disturbances would be limited because only slopes less than or equal to 25 percent would be entered with ground-based equipment. Retention of large diameter snags within RHCAs would occur. The green-line characteristics would not be compromised in RHCAs and thus stream channel and sensitive area integrity would be maintained.

3. Maintain or restore instream flows to support desired riparian and aquatic habitats, the stability and effective function of stream channels, and the ability to route flood discharges.

Thinning of the RHCAs will reduce transpiration rates and interception. If transpiration rates are reduced, runoff and groundwater infiltration could increase. Interception of rain, snow and the subsequent evaporation also effects water availability. Reduction of the canopy cover and removal of conifers throughout the RHCA will initially reduce the interception of precipitation and possibly provide more water to meadows and wetlands. Runoff may increase in the short term. This additional water may increase baseflow to perennial streams and extend intermittent stream flow further into late spring or early summer.

The main objective is to reduce the potential for stand-replacing wildfires and thus retain the RHCA's desired riparian and aquatic habitats, effective stream channel function, and the ability to route flood discharges. In-stream flows would be assessed during equipment operations, with respect to drafting requirements.

Within RHCAs, the green-line would be preserved and remain unaffected by harvest activities. Within the immediate riparian areas, physical effects derived from in-channel large woody debris (LWD) would be sustained, as no natural in-channel debris would be removed. Future recruitment of LWD would be encouraged through release of the existing conifers, and the snag retention standards for channel morphology, channel function, and bank stability. The effect of water diversion on future instream flow is beyond the scope of this project.

4. Maintain or restore the natural timing and variability of the water table in meadows and wetlands.

Transpiration is a function of the density, root mass, and size of existing vegetation. If transpiration is reduced, then runoff and groundwater infiltration could increase. Interception of rain, snow and the subsequent evaporation also effects water availability. Reduction of the canopy cover and removal of conifers throughout the RHCA will provide more water to sensitive areas. This additional water will increase baseflow to perennial streams and extend intermittent stream flow further into late spring or early summer.

Activities proposed in the project area are not expected to negatively impact the timing and variability of water tables within sensitive areas. All RHCA sensitive riparian areas (springs, seeps, and wetlands) would be protected by a 25 foot buffer from the edge of the riparian area or wet perimeter of the soil, whichever is greatest and through the implementation of applicable best management practices (BMPs).

Wet areas and green-lines would not be entered. Ground based equipment would only be allowed on stable soils and slopes less than or equal to 25 percent within RHCAs.

5. Maintain or restore the diversity and productive nature of native and desired non-native plant communities in the riparian zone.

Riparian areas are often hotspots for plant diversity. Riparian vegetation plays a vital role in the ecological functioning of the riparian system, which includes: stabilization of stream banks; delivery of large woody debris to stream habitats; filtration of sediment; and maintenance of water quality. Thinning of conifers and retention of all hardwood species within RHCAs would reduce competition and improve diversity of existing riparian plant communities.

If left untreated, noxious weeds can pose a significant threat to riparian communities due to their ability to displace native species. Implementation of standard management requirements (appendix H) and the proposed noxious weed treatment measures would reduce the risk of noxious weed spread into riparian areas and protect the diversity and productivity of riparian plant communities.

6. Maintain or restore riparian vegetation to provide an amount and distribution of large woody debris characteristic of natural aquatic and riparian ecosystems.

Large woody material adds structure to stream channels and creates fish habitat. It also provides habitat for small burrowing mammals and acts as a reservoir, retaining moisture throughout the summer months. A host of organisms, including several nonvascular plants, are supported by this moisture. Another benefit of large woody material is that it provides nutrients to the ecosystem over the long term through the process of decomposition.

Thinning of the RHCAs will return the project area to a level of stocking and health that is more closely related to its historic condition. While volume of wood per acre may be near historic levels, it is in the boles of numerous small, less fire resistant trees. Removing the ladder fuels will encourage the stand to return to its natural state and greatly enhance it by reducing competition for nutrients, water, and sunlight.

Within treatment units, the objective is to reduce overstocked fuel concentrations. Thinning within RHCAs may release the residual conifers and deciduous trees thus stimulating growth. LWD retention standards would be implemented. Potential recruitment of LWD into the stream channel would be retained and enhanced. There would be a reduction in the potential for stand-replacing wildfire, and therefore a greater potential of LWD retention. Prescribed underburns would occur during times of elevated moisture, resulting in less LWD consumption.

7. Maintain or restore habitat to support populations of well-distributed native and desired non-native plant, vertebrate, and invertebrate populations that contribute to the viability of riparian plant communities.

Living plants provide shade; their root systems promote bank stability and create macro-pores that promote high infiltration rates. The decomposition of plant material contributes to soil matter and composition, provides nutrients, and water storage. During thinning of the RHCAs, measures will be applied to insure ground cover levels are maintained and vegetation providing stability to channel banks is not removed. Riparian zones (specifically the green-line) and wetted soil perimeters would be identified and protected from harvest activities. Impacts would further be reduced by the application of BMPs and standard management requirements.

Vertebrates that influence the viability of riparian plant communities include pocket gophers, moles, butterflies, bats, and ground squirrels. Thinning of RHCAs will have no detrimental effect on these species, thus their populations will continue to maintain the viability of riparian plant communities.

Invertebrates contribute to the viability of riparian plant communities in many ways. They act as decomposers, shredding dead plant materials and they burrow into woody debris. Invertebrates recycle nutrients and influence soil structure. They improve soil porosity and improve oxygen-penetrating capabilities. To maintain invertebrate populations, compaction and ground cover disturbance will be minimized through the use of low ground pressure equipment and the subsoiling of the final 200 foot approaches of skid trails to landings.

Noxious weed species have the potential to affect riparian plant species indirectly through allelopathy (the production and release of plant compounds that inhibit the growth of other plants) Bais et al. 2003), as well as through direct competition for nutrients, light, and water (Bossard et al. 2000). Implementation of standard management requirements (appendix H) and the proposed noxious weed treatment measures would reduce the risk of noxious weed spread into riparian areas and protect the viability of riparian plant communities.

8. Maintain or restore riparian vegetation to provide adequate summer and winter thermal regulation within the riparian and aquatic zones.

Summer and winter thermal regulation within the riparian and aquatic zones would be maintained. Canopy cover within the RHCAs would be maintained at 50 percent on average, however this may range between 60 percent along fish bearing streams and 40 percent for non-fish bearing streams. Activities proposed in the project area are not expected to negatively impact riparian vegetation. Group selection harvest would only occur outside of RHCAs.

9. Maintain or restore riparian vegetation to help achieve rates of surface erosion, bank erosion, and channel migration characteristics of those under which the desired communities developed.

Riparian vegetation will be protected and maintained while coniferous ladder fuels are thinned. Except at designated crossings, stream banks will not be impacted by equipment and it is not expected that bank erosion will be accelerated either by equipment or by the implementation of the project. Thinning RHCAs will promote diversity and increase production of riparian communities. Burning of isolated burn piles outside of the RHCA will remove groundcover at point locations, but soil moving from these points will be trapped by ground cover immediately adjacent to the piles.

The maximum erosion hazard for soil types within the project area, ranging from moderate to very high, suggests that channel development has occurred under significant sediment loads. The riparian green-line of stream channels would not be impacted by the proposed management activities, and natural recovery processes within the streamside area would help moderate stream temperatures. Riparian vegetation may increase in vigor due to increased water yield and available sunlight. Within the immediate riparian areas, the physical effects derived from in-channel LWD would be retained, as no natural debris would be removed. Future recruitment of LWD, which is structurally important for channel morphology, channel function, and bank stability, would be encouraged through snag retention requirements and release of existing live conifers.

10. Maintain and restore riparian and aquatic habitats necessary to foster the unique genetic fish stocks that evolved within that specific geo-climatic ecoregion.

Maintenance of the riparian habitat necessary to foster unique genetic fish stocks will be accomplished by prescribing treatments that will maintain bank stability, ground cover, and sufficient shade. In all the action alternatives, no mechanical treatment will occur in the first 100 feet of all fish bearing streams.

It is expected that all action alternatives would not substantially impact fish populations within or downstream of the Keddie Ridge Project area. The best opportunity to improve channel conditions and fish habitat along these streams is through the proposed road decommissioning and the improvement of road drainage systems that are adjacent to stream channels.

Appendix F

Past, Present, and Reasonably Forseeable Future Projects

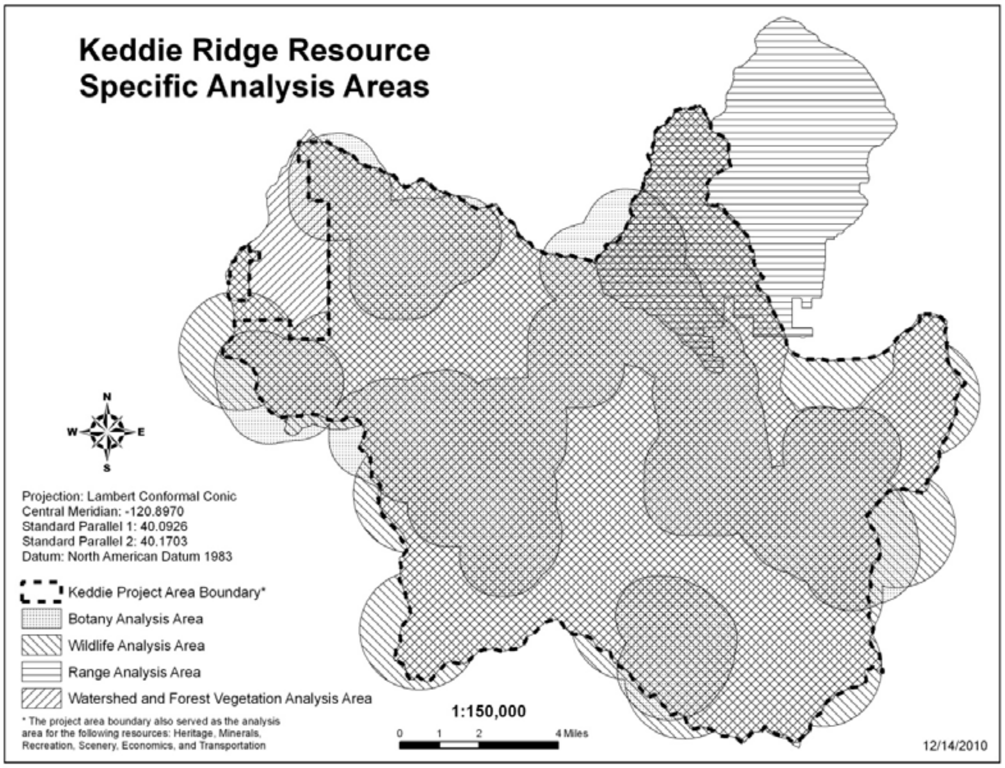
Introduction

The past, present, and reasonably foreseeable future activities described in this appendix are activities and natural events known to have already happened, are currently happening, or likely to happen within the analysis area boundaries for this project. This appendix lists projects and activities that are within one or more of the cumulative effects analysis areas for the following resources: vegetation, wildlife, botanical resources, watershed, cultural resources, range, recreation, and minerals. Analysis area boundaries are depicted in Figure 1.

This analysis relies on current environmental conditions as a proxy for the impacts of past actions—the reason is to understand the contribution of past actions to the cumulative effects of the Keddie Ridge Hazardous Fuels Reduction Project (Keddie Ridge Project) proposed action and alternatives. The current conditions reflect the aggregate impact of prior human actions that have affected the environment and might contribute to cumulative effects.

This appendix is organized by past, present and ongoing, and future projects. The projects and activities associated with specific resources are listed under each category. The sections below exhibit past vegetation management projects on public and private lands; wildfires; watershed improvement projects; wildlife projects; herbicide treatments; and present, on-going, and reasonably foreseeable future projects. For each resource area, the scale and boundaries for the cumulative effects analysis vary—these are described in Chapter 3 of the Keddie Ridge Hazardous Fuels Reduction Project Environmental Impact Statement.

Figure 1 Resource Specific Analysis Areas for the Keddie Ridge Project



Past Projects

Past Forest Service Vegetation Management Projects

A total of 38,595 acres, were treated between 1980 and 2010. Table 1 lists the acres of past vegetation management actions on public lands, by activity.

Table 1. Forest Service Vegetation Management Activities Between 1980 and 2010 that Occurred in the Four Resource Analysis Areas (Combined) for the Keddie Ridge Project.

Activity	1980	1984	1989	1990	1991	1992	1993	1994	1995	1996	1997

[1] Note: Acres shown for sanitation (salvage) represent the extent of the sale area for the given project. Under sanitation harvests, dead and dying trees are removed; however trees are not harvested from every acre. In fact the majority of acres within the sale area boundary were not subject to any harvesting.

Past Vegetation Management Projects on Private Lands

Timber Harvest Plans (THPs) were collected from California Department of Forestry and Fire Protection in April 2010. All THPs that overlap with the Keddie Ridge Project area and watershed analysis area were hand digitized into a Geographic Information System (GIS) shapefile with specific THP data attached in the attribute table. These THPs and attribute data (activity and year) are displayed in Table 2 below.

Table 2. Private Harvest Activities in Watershed Analysis Area.

	Acres of Activity by Treatment Year

Past Watershed Improvement Projects

Year	Project	Activity Description
1989-present	Wolf Creek (phase I, II, III, IV, Wolf Cr-Dunham, North	Bank stabilization and native revegetation.

	Canyon Creek (tributary to Wolf)) Restoration	

Past Recreation, Lands, and Minerals Projects

Year	Project	Activity Description
1977-1993	Calgom Mine	Exploratory drilling began in 1977. The first commercial scale Plan of Operations was approved in 1984. The mine operated continuously from November 1984 to November 1989. Active operations terminated in early 1990. Calgom Mining did some of the reclamation, but not all. The Forest Service secured their bond in 1992. The mine restoration plan was signed in May of 1993 and restoration work was completed in the summer of 1993.
2000	Ephesian Mine	Approved mining plan of operation for a lode mine.
1874-1999	Soda Rock Mine	Placer mining and removal of travertine for building stone took place in the area intermittently for over 100 years. In 1999, the Soda Rock Special Interest Area was withdrawn from mineral entry.
2005	Iron Dyke AML	Abandoned mine closure in Taylorsville area.

Past Wildlife Projects

Year	Project	Activity Description
1979-1995	Wildlife Guzzlers	Approximately 18 guzzlers installed in analysis area to improve water distribution/availability to wildlife.
1980-2007	Wood Duck Nest Boxes	Numerous wood duck boxes installed along shore of Round Valley Reservoir by USFS, boy scouts, California Waterfowl Association.
1984	Will Fire Road Closure	Closed 6 acres of road within the Will Fire burn.
1985	Keddie Ridge Road Closure	Closed 2.3 miles (5.5 acres) of road on Keddie Ridge.
1986	Beardsley Grade Broadcast Burn	Broadcast burned 110 acres of brush/oak using helitorch to improve deer winter range.
1988	Road Seeding	Seeded 1 acre of closed skid trail on Beardsley Grade for deer winter range improvement.
1989	Jura Burn	Broadcast burned 125 acres of brush/oak using helitorch to improve deer winter range.
2008	Genesee Oak	12 acres of black oak was thinned and over-mature silktassel brush was cut to improve deer winter range.

Past Herbicide Treatments

The California Department of Pesticide Regulation (DPR) requires farmers and other users of agricultural pesticides to submit site-specific documentation of all pesticide applications; these include applications to parks, golf courses, cemeteries, rangelands, forest lands, pastures, and along roadsides and railroad rights-of-way. The primary exceptions to these reporting requirements are home-and-garden use and most industrial and institutional uses (California DPR 2009). The total amount of reported glyphosate use within Keddie Ridge Project analysis areas is listed in Table 3 and Table 4 below. There was no reported use of aminopyralid or borax within any of the analysis areas.

Table 3. Total Pounds of Glyphosate (Isopropylamine Salt) Recorded within the Four Keddie Analysis Areas Between 2004 and 2008. Data are not Currently Available for 2009 or 2010.

Sub-watershed	Reported Use				
	2004	2005	2006	2007	2008
Crescent Mills			42		
Mountain Meadows					135
Upper Cooks Creek					1202
Upper Wolf Creek	34

Present and Ongoing Projects

Present and Ongoing Vegetation Management Projects within the Keddie Ridge Project Analysis Area

Maidu Stewardship Project	Project treatments include approximately 550 acres of commercial and non-commercial thinning to improve oak habitat; 405 acres of commercial and non-commercial thinning to reduce hazardous fuels, approximately 325 acres of habitat enhancement for culturally important plants. Treatments were initiated in 2006 and are expected to continue through 2016.
Canyon Dam Fuel Reduction and Forest Health Project	Approximately 147 acres of hand thinning, piling, and burning was initiated in fall of 2010 and will be completed over 3-5 years. In addition, 488 acres of mechanical thinning will be initiated in 2011 and completed over 3-5 years. Follow-up prescribed fire treatments will be initiated in 2012 and completed over 3-5 years.
Empire Vegetation Management Project	Project treatments include approximately 121 acres of group selection timber harvest; 430 acres of defensible fuel profile

	zones (DFPZs) mechanical thinning; 133 acres of individual tree selection mechanical thinning; and 144 acres of mastication. These treatments will be initiated in fall 2010 and would be completed over 3-5 years. Follow-up prescribed fire treatments will be initiated in 2012 and completed over 3-5 years.
Moonlight Fire Recovery and Restoration Project	Project treatments include approximately 330 acres of post-fire roadside hazard tree removal and 70 acres of post-fire salvage harvest. These treatments are ongoing and anticipated to be complete by the end of 2011.
Plumas Fire Safe Council Projects	These projects are located on private lands surrounding homes and are currently being implemented by the Plumas Fire Safe Council. Project treatments include approximately 294 acres of a combination of handthinning, piling, and burning, mastication, and some removal of commercial and non-commercial forest products.
Natural Resource Conservations Service (NRCS) Projects	These projects are located on private lands and are currently being implemented by the Natural Resource Conservation Service (NRCS). Project treatments include approximately 1,960 acres of a combination of handthinning, piling, and burning, mastication, and some removal of commercial and non-commercial forest products.

Present and Ongoing Recreation, Lands, and Minerals Projects

Recreation activities	Recreation activities include camping, hiking, horseback riding, mountain biking, road biking, off-highway vehicle riding, boating, swimming, fishing, snowmobiling, cross country skiing, hunting and rock hounding, picnicking, and driving for pleasure.
Recreation site maintenance	There are 2 developed recreation sites within the project area, Greenville Campground and Round Valley Picnic Area. There are also 2 dispersed recreation sites, Indian Falls and Sandy Beach, which are commonly used for swimming. Greenville Campground is operated under a special use permit with Indian Valley Community Services District. Developed and dispersed recreation site maintenance requires hazard tree removal, graffiti removal, pile burning, replacing signs, fire rings, tables and older

	buildings.
Trail maintenance	There are approximately 7 miles of non-motorized system trails within the Keddie Ridge Project area. These trails include Peters Creek Trail, Round Valley Interpretive Trail, and Indian Falls Interpretive Trail. Annual trail maintenance work consists of clearing hazard trees, maintaining water bars or other erosion control devices, and maintaining or replacing signs. Work is typically accomplished by force account crews and volunteers.
Personal use woodcutting permits	Woodcutting for personal use is permitted throughout the Plumas National Forest. The following is a list of the number of personal use permits sold on the Mt. Hough Ranger District for the past nine years. It is estimated that 20 percent of the District's permit sales are within the Keddie Ridge Project area. 2001 – 2,577 permits for an estimated 5,154 cords 2002 – 2,461 permits for an estimated 4,922cords 2003 – 2,154 permits for an estimated 4,308 cords 2004 – 1,940 permits for an estimated 3,880 cords 2005 – 2,475 permits for an estimated 4,950 cords 2006 – 2,651 permits for an estimated 5,302 cords 2007 – 2,499 permits for an estimated 4,988 cords 2008 – 3,096 permits for an estimated 6,192 cords 2009 - 2,871 permits for an estimated 5,742 cords
Commercial use woodcutting permits	The following is a list of the number of commercial permits sold on the Mt. Hough Ranger District for the past 9 years. It is estimated that 20 percent of the District's commercial permit sales are within the Keddie Ridge Project area. 2001 – 160 permits for an estimated 2,400 cords 2002 – 135 permits for an estimated 2,025 cords 2003 – 92 permits for an estimated 1,380 cords 2004 – 83 permits for an estimated 1,245 cords 2005 – 255 permits for an estimated 3,825 cords 2006 – 329 permits for an estimated 4,935 cords 2007 – 372 permits for an estimated 5,580 cords 2008 – 774 permits for an estimated 9,000 cords 2009 – 1,609 permits for an estimated 16,000 cords
Christmas tree permits	The following is a list of the number of Christmas tree permits sold on the Mt. Hough Ranger District for the past 9 years. It is estimated that 25

percent of the Mt. Hough Ranger District's permit sales are within the Keddie Ridge Project area.

2001 – 2,062 permits
2002 – 2,348 permits
2003 – 2,499 permits
2004 – 2,282 permits
2005 – 2,320 permits
2006 – 2,047 permits
2007 – 2,364 permits
2008 – 2,136 permits
2009 – 1,736 permits

Abandoned mines — Two identified abandoned mineshafts exist within the project area. Open shafts may pose a direct hazard to forest users, Forest Service personnel, and Forest Service contractors.

Active mining claims — There are approximately 168 active mining claims in the project area. The Mt. Hough Ranger district currently administers 3 active plans of operation and 4 notices of intent for those active claims.

Special uses — There are 39 special uses that occur in the project area. These permitted uses include 3 road easements, 4 power lines, 1 railroad right-of-way, 11 waterlines, 1 telephone line, 1 barn, 1 private residence, 2 irrigation ditch permits, 1 transfer station permit, 2 livestock areas, 1 natural resource monitoring permit, 1 weather station, 1 weather modification device, 1 storage yard, 2 industrial microwaves, 1 reservoir, 1 stream gauge station, 1 private mobile radio service, 1 commercial radio service, 1 campground concession permit, 1 group use permit, and 2 recreation events. These forest uses require maintenance of the permitted area by permitees which may include activities such as hazard tree removal, brush removal, road maintenance, and replacement of improvements.

Present and Ongoing Grazing Activities

Allotment	Number of Acres	Acres within Analysis Area	Status		
			Status/Kind	Number	Season
Lights Creek	29,929	611	Active	24 Pair 'On' 16 pair 'Off'	6/1-9/1
Taylor Lake	26,920	235	Vacant		

Present and Ongoing Botany Projects

Webber's Milkvetch (*Astragalus webberi*) Habitat Improvement Project	This project is located approximately 0.3 miles south of Taylorsville and is adjacent to National Forest System (NFS) road 23N59. It includes treatment of 7.5 acres of NFS land using a combination of hand thinning, piling, pile burning, and prescribed fire to enhance habitat for Webber's milkvetch, a Region 5 Sensitive plant species.
Noxious Weed Mechanical Treatment Project	As a part of this project, 10 yellow starthistle infestations, covering approximately 1.8 acres, are treated on an ongoing basis within the Keddie Ridge Project analysis area. Treatments consist of hand pulling and cutting with a string trimmer (i.e. weed whacker).

Present and Ongoing Herbicide Treatments

No herbicide treatments are currently being conducted on NFS lands within the Keddie Ridge Project area. For an estimate of use on private lands, refer to Table 3 and Table 4, which describe past pesticide application within the Keddie Ridge Project analysis areas.

Future Projects

Future Fuels and Vegetation Management Projects within the Keddie Ridge Analysis Area

Year	Project	Activity Description
2013	Belden HFQLG Project	Project Treatments include: Approximately 605 acres of DFPZ treatments, 105 acres of area thinning treatments, and potentially 81 acres of group selection.
2011	Keddie Ridge Roadside and Deck Salvage Sale	This project proposes to remove three decks on NFS roads 27N19 and 27N19X created during the Moonlight Fire of 2007. Additionally, this project would remove roadside hazards along nine miles of NFS roads 28N32, 27N19, and 27N19X.

Fuel Treatment Maintenance within the Keddie Ridge Project Area

Defensible fuel profile zone (DFPZ) maintenance would be a reasonable and foreseeable future activity occurring within the Keddie Ridge Project area. These activities would be designed to maintain low surface fuel loadings, low fire intensities, and low rates of spread. This discussion incorporates, by reference, the Herger-Feinstein Quincy Library Group Forest Recovery Act Final Environmental Impact Statement and Final Supplemental EIS (HFQLG FSEIS) (USDA 2003a). Surface fuel reduction activities would include, but not be limited to, prescribed fire, mastication, and piling and burning of residual slash.

The Forest Service would assess the need for DFPZ maintenance treatments approximately five to ten years after the completion of the initial mechanical and fire activities proposed in the Keddie Ridge Project. It is expected that maintenance activities would take place as described in the HFQLG FSEIS, and further refined by on-site information available at the time that maintenance would be proposed. Specific decisions about maintenance for a particular DFPZ (timing of entry and treatment method) would be made at the time DFPZ maintenance is deemed necessary (HFQLG FSEIS, page 3).

Future Watershed Treatments

Year	Future Activities	Activity Description
2010	Wolf Creek Restoration	Bank stabilization and native revegetation.

Future Grazing Activities

A Plumas National Forest Range NEPA (National Environmental Policy Act) Strategy and Implementation Plan was signed by the Forest Supervisor on December 16, 2005. Through plan implementation, the Forest will analyze and document range NEPA projects on all active allotments. The Lights Creek Allotment is currently scheduled for analysis in 2016. No range improvements are anticipated in the meantime. End of season use monitoring (meadow use, riparian shrub use, and stream bank alteration) is done each year.

Future Recreation, Lands, and Minerals Projects

Year	Future Activities	Activity Description
2010	OHV Route Designation	The Plumas National Forest Motorized Travel Management Project Final Environmental Impact Statement and Record of Decision was completed and signed in fall of 2010. This decision added 234 miles of trails to the existing National Forest Transportation System, creating a total of 4,482 total miles of road and trail access on the Forest. Of that total, 4,118 are available for passenger car use; 4,383 are available for 4-Wheel Drive use; 3,802 are available for unlicensed All Terrain Vehicles (ATV) use; 3,855 are available for unlicensed motorcycle use; and, 4,482 are available for licensed motorcycle use. A subset (165 miles) of the 234 miles will be available immediately while the remainder will need maintenance before they can be used. Implementation of the Plumas National Forest Motorized Travel Management Project will occur when appeals have been resolved and a Motor Vehicle Use Map (MVUM) is published. The MVUM will show which routes are available for use by what types of vehicles and any seasonal restrictions that may apply. Pending any appeal resolution, the MVUM is expected in the spring of 2011. Until then, the current Forest Order regulating use remains in place.
2011	Recreation	The Mt. Hough Ranger District has plans to complete a Cycle 10 Resource Advisory Committee (RAC) Project in Greenville Campground by replacing a restroom with a sweet smelling vault toilet.
2011	Lands	The Plumas National Forest is seeking a permittee to operate and maintain the Greenville shooting range under a special use permit. The forest has started verbal negotiations with a potential permittee.
2011	Abandoned mine land reclamation	The Plumas National Forest will likely be reclaiming the two know abandoned mine sites within the project area during 2011.

2010	Mining Plans of Operation	There are six potential future mining operations that would be approved through a mining plan of operation.

Appendix G

Public Comments, Response to Public Comments, and Issue Identification

Introduction

The following appendix displays Forest Service responses to public comments on the Keddie Ridge Hazardous Fuels Reduction Project released January 2011. This appendix includes (1) a table listing the name and location of the commenter, the organization or entity each commenter represents, and the date of the comment; and (2) a narrative of comment statements and Forest Service responses organized by resource as presented in chapter 3. The comment statement is taken from the comment letters. A complete copy of each letter received is available at the Mt. Hough Ranger District, Quincy, CA, and are hereby incorporated by reference.

Summary of Public Comments Received

The Responsible Official received verbal or written comments from three agencies and seven organizations. The Council on Environmental Quality (CEQ) regulation 40 CFR 1503.4 states that an agency preparing a final environmental impact statement shall assess and consider comments both individually and collectively, and shall respond by one or more of the means listed below, stating its response in the final statement. Possible responses are to:

1. **Modify alternatives including the proposed action,**
2. **Develop and evaluate alternatives not previously given serious consideration by the agency,**
3. **Supplement, improve, or modify its analyses,**
4. **Make factual corrections,**
5. **Explain why comments do not warrant further agency response.**

Table 1. Commenters on the Keddie Ridge Hazardous Fuels Reduction Project Draft Environmental Impact Statement.

Responses to Public Comments

Below are comments and responses on the Keddie Ridge Hazardous Fuels Reduction Project Draft Environmental Impact Statement released in January 2011. These comments are sorted by comment number in order of appearance under chapter 3 "Affected Environmental and Environmental Consequences (FVFFAQ – Forest Vegetation, Fuels, Fire, and Air Quality; WL – Wildlife: Terrestrial and Aquatic; WT – Watershed (Soils and Hydrology); B – Botanical Resources; E – Economic and Social Environment; AD/S – Alternative Development/Selection).

Forest Vegetation, Fuels, Fire, and Air Quality (FVFFAQ)

For additional information regarding responses to comments raised during the scoping period, during the DEIS comment period, and after the DEIS comment period, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality report, Appendices F, G, and H, respectively.

1. **"The following specific information for each of the prescriptions would (be) helpful to identify if the concepts in the GTR are reflected by the post-treatment stand attributes: #1 Breakdown of trees removed by diameter class and by species for each unit."** (Thomas and Silvas-Bellanca, SFL, pg. 1)

Response: Please refer to the Final Environmental Impact Statement (FEIS), Chapter 1, Purpose and Need for desired conditions for fuels reduction and forest health. Please refer to the FEIS Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Measurement Indicators and Environmental Consequences section including comparison of alternatives for a discussion on the measurement indicators used to analyze alternatives effects and effectiveness in meeting desired conditions in terms of forest structure and composition, landscape heterogeneity, and fuels and fire behavior. In addition please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendices A and C for existing pre-treatment and residual post-treatment conditions. Breakdown of trees and species removed are a poor indicator of whether desired conditions or concepts within the GTR are met because this focuses on what is being removed, not what conditions are left after the treatment. Post-treatment stand conditions are far more applicable to how well desired conditions are met. The FEIS Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Environmental Consequences section provides a discussion of post-treatment stand conditions with regards to the measurement indicators. The FEIS, Appendix A, Tables 2, 4, 6, and 8 also display more unit specific post treatment stand conditions and ranges in conditions after treatment for each alternative. In addition, during the comment period, FVS outputs for each stand and prescription were provided showing number of trees per acre by diameter class both before and after treatments. Lastly the FEIS, Appendix D, Economic Analysis section provides a relative estimate of volume of harvested trees by species both greater than 24 inches in diameter and less than 24 inches in diameter by alternative.

2. **"The following specific information for each of the prescriptions would (be) helpful to identify if the concepts in the GTR are reflected by the post-treatment stand attributes: #2 Breakdown of slope positions for each prescription and how that corresponds to retention on a per acre basis."** (Thomas and Silvas-Bellanca, SFL, pg. 1)

Response: Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C, Alternative A, Implementation of Within-stand Level Heterogeneity section. The tree selection guidelines describe how treatment intensity and corresponding reduction in stand density should vary with, among other variables, aspect. This section includes two tables; the first describes the varying amount of aspect for each unit that would receive a mechanical thinning treatment; the second table displays both average and a range in stand level conditions that correspond with maximum and minimum canopy cover retention guidelines in the silvicultural prescription for each unit.

3. **"The following specific information for each of the prescriptions would (be) helpful to identify if the concepts in the GTR are reflected by the post-treatment stand attributes: #3 We'd like a more specific description of the snag retention levels in each unit. The discussion of 4-6 snags/acre is contrary to natural (variable) snag production levels in nature that the GTR is striving to replicate. In Scott Stephen's work in the Sierra Martir, the average snag levels only occurred on 12 percent of the acres in his research acre. Presenting field markers with an average/ac marking requirement creates a homogenous landscape, not a restored, diverse outcome. We are looking for something that supports the notion of heterogeneity in the unit designs."** (Thomas and Silvas-Bellanca, SFL, pp. 1-2)

Response: Please refer to the FEIS, Chapter 2, Alternatives Considered in Detail, Design Criteria common to all action Alternatives, for snag retention design criteria; the FEIS, Chapter Forest Vegetation, Fuels, Fire, and Air Quality, Environmental Consequences, Effects common to all action alternatives, Direct and Indirect effects section of timber harvest for effects to snags, and the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C, Alternative A, Implementation of Within-Stand Level Heterogeneity, Tree Selection Guidelines, Item #7 (Snags) section for tree designation guidelines for snags. Proposed treatments would not designate snags for removal unless those snags pose a hazard to infrastructure or treatment operations. The treatments proposed under the Keddie Ridge Project would retain four to six snags per acre (greater than 15 inches in diameter and 20 feet in height) in accordance with the 2004 SNFPA ROD (Table 2, page 69) (USDA 2004b). Incidental removal of snags may occur for operability and safety; however guidelines set forth in the Pacific Southwest and Plumas National Forest Product Theft Detection and Investigation Plan would be used to ensure that operability, safety, and minimum snag densities would be met. Snags designated as hazards would meet guidance provided in the Plumas National Forest Hazard Tree Abatement Plan, OSHA regulations governing logging operations (29 CFR 1910.266), and the Forest Service Manual 2450 (Timber Sale Contract Administration) policy.

4. **"Basal area retention levels appear to take the approach that has 150 sq ft BA average across most of the project. Most of the early stand density literature is focused on young, fast growing even-aged stands and does not support a more ecological GTR-220 approach of variable clumping with gaps. Averaging BA and presenting "averaging" in the marking instructions will lead to simplification of stand structure and increased homogeneity…the thing we are trying to avoid. Clumped retention and variable BA retention, particularly around large tree groups (see attached photo) is one of the primary objective in the GTR Dinkey Creek project planning documents we presented to you during scoping. We need to better understand how (and if) these concepts are reflected in the Keddie project. A more specific breakdown of the levels of**

retention that will be provided in groups, pg. 43 of the Forest Vegetation, Fuels, Fire, and Air Quality report elude to various levels of retention in CWHR 4 stands and CWHR 5 stands, but no values are given of these various retention levels." (Thomas and Silvas-Bellanca, SFL, pg. 3: #4)

Response: Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality Section, Effects Analysis Methodology, Measurement Indicators. Basal area is used as a measurement indicator of how well alternatives would or would not meet desired conditions associated with improving forest health. The threshold of 150 square feet per acre provides context and scale to this measurement indicator and is not a design element or design criteria of proposed treatments. The FEIS, Chapter 2 Alternatives, describes alternatives, proposed treatments, silvicultural prescriptions, and design criteria.

The threshold of 150 square feet of basal area per acre, above which density second-growth ponderosa pine stands are considered susceptible to bark beetle-induced mortality, was first suggested by Sartwell (1971) and his subsequent research (Sartwell and Steven 1975, Sartwell and Dolph 1976). Oliver (1995) found that Sartwell's threshold of 150 square feet of basal area per acre "above which density stands are susceptible to attack by bark beetles appears to be a reasonable average value for California."

Landram (2004) used basal area as a metric to develop insect risk thinning guidelines for the eastside, transition, and westside zones of the Plumas National Forest. For the transition zone (Where the Keddie Ridge Project is primarily located) the insect risk thinning guides also suggest thinning to 150 square feet of basal area per acre. It is also worth noting that this threshold appears in line with a majority of the reference conditions described for the project area (Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, Estimates of forest structure for pine dominated and mixed conifer forests in California and northern Mexico adapted to an active-fire disturbance regime.) Consequently, this metric is used in the analysis to quantify and compare the relative effectiveness of the alternatives and corresponding treatments in meeting desired conditions for forest health.

Using stand level average metrics as a threshold to compare alternatives would not result in "simplification of stand structure and increased homogeneity." As shown in the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C, Implementing Within-Stand Variability, Tree selection guidelines would be used to enhance heterogeneity and "key off" micro site and wildlife habitat structures. Item # 4c describes basal area guidelines and how basal area retention would vary depending on clump, gap, and matrix locations. In addition, the FEIS Appendix A, tables 2, 4, 6, and 8 display the stand level range of basal areas corresponding to the canopy cover ranges for each prescription by alternative. All proposed treatments would meet basal area retention standards as directed by the SNFPA 2004 ROD, table 2.

5. **The Appendix D-2 suggests 132 mbf of >24" PP and SP are going to be harvested in the project. How is this consistent with ecological restoration that should be targeting the retention of these tree species and sizes?** (Thomas and Silvas-Bellanca, SFL, pg. 3: #5)

Response: Please refer to the FEIS, Appendix D, Economic Analysis, Tables 1through 4. Table 1 estimates that treatments under alternative A could produce 132 mbf of sawlog volume in ponderosa pine and sugar pine trees greater than 24 inches in diameter. Table 4 estimates that treatments under alternative E could produce 1,157 mbf of sawlog volume in ponderosa pine and sugar pine trees greater than 24 inches in diameter. Tables 2 and 3 estimate that no sawlog volume in ponderosa pine and sugar pine trees would be harvested. These volume estimates are based on FVS modeling using simulated prescriptions and due to the uncertainty in modeling estimates, these results are best interpreted in a relative rather than an absolute sense. These tables indicate opportunities to harvest ponderosa pine and/or sugar pine greater than 24 inches do exist within stands in the project area under these prescriptions; however, 1) these opportunities would be much more limited under alternative A than alternative E, and 2) these opportunities would generally be discouraged given the preference to retain these trees to best meet desired conditions.

Under alternative A, these trees could account for approximately 1.3 percent of the total volume to be harvested and could equate to approximately 1 tree every 7 to 181 acres, depending on the stand, whereas under alternative E removal of these trees would increase by nearly 9 times more than alternative A. Under alternative E, these trees could account for approximately 7.5 percent of the total volume to be harvested and could equate to approximately 1 tree every 3 to 5 acres.

In addition, retention of ponderosa and sugar pine greater than 24 inches is preferred to meet desired conditions. While the FVS modeling and economic analysis indicates that given stand conditions, some opportunities to remove these trees exist, the on the ground rationale for designating these trees would follow those few instances described by North et al. (2009), Addendum, page vii.

6. **"In the analysis of Forest Vegetation, Fire, Fuels, and Air Quality our main concern is that the concepts of the GTR-220 are not fully captured by the averaging metrics used to compare Alternatives. Further, the target stand condition although weighted by species reduces BA to 150 ft2/ac on 70 percent of stands treated mechanically (p. 77 DEIS) and does not support the intentions of proposed action to use the concepts of the GTR-220. Comments from Malcolm North on the Keddie project point out that averaging is unlikely to capture heterogeneity. "However much of what historic forests were like and the conditions suggested by GTR 220 are for a high variability in density that SDI averages are unlikely to capture." Averaging SDI also seems to suggest spacing of larger trees, realigning the proposed alternative with the HFQLG alternative. SFL could better understand the intentions of the DEIS if general criteria were presented in the document on how and when larger trees will be thinned with more developed discussion of how this will enhance and improve habitat values and increase fire resiliency. Given the shortage of larger tree-dependent high quality it is hard to understand the emphasis on even spacing, particularly of larger trees."** (Thomas et al., FL, pg. 10)

Response: Please refer to response to comment FVFFAQ #4. The threshold of 150 square feet of basal area is used as a measurement indicator threshold, above which stands may be more susceptible to bark beetle induced mortality. This measurement indicator is used to compare the relative differences of the alternatives in meeting the purpose and need for forest health, it is not used as a design criteria. Desired conditions include heterogeneity and diverse forest structures at multiple scales: at the micro site or within stand variability, at the stand level, and at the landscape level. Such heterogeneity, particularly at the within stand level, may be represented by large ranges within stand conditions; however, there is considerable utility in forest management in describing and comparing average conditions, just as the mean is used in statistics to give context to ranges in variance and determine levels of significance.

Under alternative A, 70 percent of the mechanically treated stands would have average conditions which would be below the threshold of 150 square feet per acre. This indicates that these stands would meet desired conditions for forest health in terms of improving forest resiliency to insect mortality. While forest structure within these stands would be variable with large ranges in canopy cover and basal area, on average, at the stand level, these stands would have densities reduced such that susceptibility to insect mortality would be reduced.

These stand level thresholds do not "suggest spacing of larger trees, realigning the proposed alternative with the HFQLG alternative" or imply homogeneity. Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report Appendix C, Implementation of within-stand level heterogeneity section. For example, the figure from Terry and Chilingar (1955) under Appendix C, Tree Selection Guidelines, Item #2, displays how a certain canopy cover guideline or threshold may vary by a clumped or even distribution. Likewise with basal area, a quantified average guideline or threshold does not implicitly lead to homogeneity. Distributions depend on implementation of such threshold or guideline, and such conditions may be met while mutually emphasizing concepts of heterogeneity. The Forest Vegetation, Fuels, Fire, and Air Quality Report Appendix C, Implementation of within-stand level heterogeneity section provides direction on how such desired conditions may meet canopy cover and basal area guidelines while enhancing heterogeneity. Tree selection guidelines are provided as general criteria on "how and when larger trees will be thinned with more developed discussion of how this will enhance and improve habitat values and increase fire resiliency."

In addition, please refer to the response to comment FVFFAQ #7.

7. **Basal areas and stand densities are based on even-aged ponderosa pine stand data: We remain concerned about information presented regarding desired stand density and basal area in Chapter 3 (p. 46-47) because while heterogeneity and diversity are mentioned in the treatments there is also a consistent message of retaining very low densities throughout the project area (also noted in comments from Brandon Collins, Appendix B, p. 109). Both these ideas seem to be in conflict throughout the analysis.** (Thomas et al., FL, pg. 10)

Response: Please refer to the response to comment FVFFAQ #6. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions. In the section on reference conditions, two important concepts are highlighted by studies on reference conditions: 1) the heterogeneity of forest structure, and 2) the low stand densities of forest structure. Clearly, the concept of low densities is not mutually exclusive from the concept of heterogeneity. While reference conditions indicate a large ranges in both trees per acre and basal area per acre, these studies also indicate that average stand level densities were low. Collins et al. (2011) serves as a good example of this; while recognizing considerable variation in forest structure, the authors also emphasize the need for creating low density structures. Collins et al. (2011), Figure 3 shows that over 60 percent of the historical lots had derived canopy covers less than 30 percent canopy cover and 96 percent of lots had canopy covers less than 40 percent canopy cover.

Large ranges in forest structure indicates a high degree of heterogeneity that may be characterized by a wide range of dense conditions and open conditions, but low average stand densities indicate that this forest structure – which is thought to be more resilient - had relatively higher proportions of open forest conditions than dense forest conditions. Therein lies the utility and necessity to analyze both the average and the ranges with regards to forest structure and heterogeneity; while the range indicates the wide ranges in conditions, the average puts the relative proportions of these conditions into context.

Particularly in terms of climate change, studies such as Hurteau and North (2009), Stephens et al. (2009), and Battles et al. (2008) all suggest that, for the Sierra Nevada mountains, maintaining lower density stands, on average, dominated by large fire-resistant trees may be better resilient to climate induced trends described for forests with active-fire disturbance regimes.

8. **Basal areas and stand densities are based on even-aged ponderosa pine stand data: While the discussion on stand density and basal area effectively summarizes key research, the DEIS seems that it focuses entirely on stocking levels for ponderosa pine type. We believe that applying a threshold of 150 ft2/acre basal area or assigning an SDI of 270 (60 percent of maximum of 450) is inappropriate for mixed conifer stands. We also note that this approach is not consistent with that taken on other national forests. The values reported in yield tables for mixed-conifer stands are significantly greater than the numbers associated with pine stands. It is inappropriate to consider a stocking threshold of 60 percent as a level to never exceed when the Keddie project and the 2010 HFQLG Status Report monitoring show very low levels of snags and large woody material. Levels so low that the Plumas National Forest is failing to met standards and guidelines for the retention of these important resources. Mortality is a critical part of forest dynamics. It is important to a vast array of wildlife species and plays a critical role in overall forest health. Also, as pointed out in Collins comments, "…the period encompassed by these studies (referring to Appendix A of the Forest Vegetation, Fire, Fuels, and Air Quality specialist report pg. 100-101) corresponds with a fairly narrowly focused view of forest management that did not recognize the role or importance of natural disturbance in maintaining healthy forests." This is a key issue in the development of reference conditions, and it identifies the key question of how valid are these conditions without recognizing the importance of disturbance in the landscape.** (Thomas et al., FL, pg. 10)

Response: Please refer to the response to comments FVFFAQ #6 and #7. Also, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, Stand Density. An SDI of "270 (60 percent of maximum of 450)" was not assigned to mixed conifer stands. The Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, discloses that: "The combination of Long and Shaw's work, with first-hand familiarity of the forests within the project area, suggest a fairly conservative maximum SDI of 450, which is the value used for ponderosa pine in this analysis. This is based on the latest research by Long and Shaw (In review) for the pine dominated mixed conifer forests of the Sierra Nevada (Long, personal communication, Shaw, personal communication), and considers the desired low density conditions, and the relatively lower site of the project."

The Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, further describes that "For the Keddie Ridge Project, a site-specific maximum stand density was calculated for each stand using the Forest Vegetation Simulator (FVS), which calculates maximum stand density weighted by the "proportion of basal area each individual species represents in the stand" (Dixon 2002) as described by Hann and Wang (1990). This may be a more appropriate measure of maximum stand density as it considers site-specific species composition reflected in the existing condition. While a maximum stand density index of 450 is used for ponderosa pine in this analysis, the individual stand maximum stand densities are higher – this is driven by the presence of shade tolerant species such as Douglas fir and white fir which have higher maximum stand density indices. This approach is well accepted as a component of the Forest Vegetation Simulator (Dixon 2002) and is consistent with approaches described by the latest silviculture and ecology texts (Tappeneir et al. 2007) and the scientific literature (Hann and Wang 1990, Shaw 2006)."

Using basal area threshold (150 square feet per acre) and stand density threshold (60 percent of maximum SDI) are entirely consistent with Region 5 direction for designing thinning for fuel reduction and forest health objectives (Landram 2004, Blackwell 2004). Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Effects Analysis Methodology, Measurement indicators for Forest Vegetation section. The insect risk thinning guidelines developed specifically for the Plumas NF, Transition Zone (where the Keddie Ridge Project is primarily located) suggest thinning to 150 square feet per acre.

In addition, direction provided by the Regional Forester Jack Blackwell on Conifer Density Management for Multiple Objectives (2004) is to design thinnings to "ensure that that density does not exceed an upper limit (for example: 60 percent of maximum stand density index)" and to "ensure that this level will not be reached again for at least 20 years after thinning."

Furthermore, use of stand density concepts for forest and fuels management, particularly for Sierra Nevada Forests, is widely discussed in scientific literature. Sherlock's 2007 General Technical Report (PSW GTR-203) titled "Integrating Stand Density Management with Fuel Reduction" specifically discusses how stand density management concepts are directly applicable to fuel and forest health treatments for the Sierra Nevada forests and how this is congruent with the 2004 SNFPA ROD and FEIS (USDA 2004a, 2004b). Oliver et al. (1996) in the Sierra Nevada Ecosystem Project devotes an entire chapter to "Density Management of Sierra Forests" which describes "objectives for regulating stand density in the Sierra Nevada forests are ecological as well as managerial." The linkages between silviculture and ecology are widely discussed by Long et al. (2004) for a wide range of forest ecosystems. In addition, threshold relationships between stand density and insect mortality are also widely discussed in the scientific literature for western forests including Fettig et al. (2007), Ferrell (1996), Oliver (1995), Negron and Popp (2004), and Negron et al. (2009).

For a discussion on yield tables, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, Reference Conditions section. Dr. Collins' comments points out that the yield tables, which tend to describe denser forest structure were focused on stand normality and "well-stocked stands." These yield tables did not include low density stands because, as Dr. Collin's comments point out, that "the period encompassed by these studies (referring to Appendix A of the Forest Vegetation, Fire, Fuels, and Air Quality specialist report pg. 100-101) corresponds with a fairly narrowly focused view of forest management that did not recognize the role or importance of natural disturbance in maintaining healthy forests." Consequently, his comments highlight that yield tables were biased toward denser stands, yet reference conditions indicate that many stands were, on average, of much lower density under a natural active-fire disturbance regime contrary to the commenter's assertion that yield tables indicate that stands were much denser.

The commenter discusses the concepts of managing for 60 percent of maximum stand density index, and recruitment of large woody debris. With regards to managing for 60 percent of maximum stand density index and large woody debris recruitment. The Keddie Ridge Project does not propose that a "stocking threshold of 60 percent as a level to never exceed". Please see response to comment FVFFAQ #8 and Blackwell (2004). In addition, please see the response to comment FVFFAQ #3 and please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C, Alternative A, Tree Selection Guidelines Item #7 section. Under the Keddie Ridge Project snags would not be designated for removal unless it is a hazard tree, and where large down woody desired conditions are not met, snags would be left for wildlife habitat.

Lastly, with regards to snags and snag recruitment, there are two concepts which are applicable to the project. The first is that managing stands below 60 percent of maximum stand density does not equate to zero tree mortality. Natural background levels of mortality would still be expected to occur. This is evident from reference conditions that indicate that while stands may have low average stand densities, a wide range in conditions – or heterogeneity – in combination with natural disturbance regime events such as fire, provide for natural background levels of mortality.

The second concept involves scale and intensity. The Keddie Ridge Project proposes to treat approximately 11 percent of the National Forest System (NFS) lands within the FVFFAQ analysis area. Of this, nearly half of the treatments involve hand thinning, piling, and burning or prescribed fire treatments which would not notably effect recruitment of larger snags (greater than 15 inches dbh and greater than 20 feet tall). In fact, the proposed 1,456 acres of low to moderate prescribed fire treatments would likely create new snags directly through fire-induced mortality and indirectly through delayed mortality as a result of fire-injury and predisposal to insect attack.

The FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Affected Environment, Figure 2 indicates that a large portion of NFS lands within the analysis area are dominated by closed canopy mid to late seral stands (represented by CWHR 4M, 4D, 5M, and 5D), which are characterized by relatively higher stand densities and higher potential for mortality and snag and large down woody debris recruitment. Furthermore, the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Environmental Consequences, Comparison of Cumulative Effects, Table 49 indicates that these CWHR types and corresponding conditions would be reduced by 7 to 12 percent dependent on alternative. Considering 1) the context, scale, and dispersion of treatments that reduce stand densities, 2) the expected continued background levels of mortality within these units, 3) snag creating effects of proposed prescribed fire treatments, 4) the persistence of high stand density conditions and expected and continued mortality outside of treatment areas, and 5) treatment design criteria to retain levels of snags and large down woody debris, including tree selection guidelines that address retaining green decadent trees with wildlife structures, measures have been incorporated into the project design to minimize reductions in, maintain retention, and promote recruitment of snag densities and large down woody debris.

9. **Basal areas and stand densities are based on even-aged ponderosa pine stand data: Further complicating this issue, Long and Shaw (2005), which is cited numerous times to suggest that SDI of 450 was appropriate for ponderosa pine across western states (Appendix A of Forest Vegetation, Fire, Fuels, and Air Quality report pg. 96); however this same study also identifies that this approach should be used with caution (See page 214). We are particularly concerned because the Long and Shaw 2005 paper had very limited sampling of Ponderosa pine plots in California (See Table 1, p. 206) used to inform the paper. Relying on this paper to support the low BA outcomes in the Keddie project skews desired conditions in a direction inappropriate for mixed conifer stands in the project area. Relying on Oliver (2005) pine mortality data for the Keddie project is also inappropriate since that information is derived from even-aged Ponderosa pine stands in California. Please explain in detail why thresholds for even-aged pine stands are used as desired conditions and to drive management for mixed-conifer stands.** (Thomas et al., FL, pg. 11)

Response: Please refer to response to comment FVFFAQ #8. Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Measurement Indicators, Forest Vegetation, Relative Density; and the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A. Recent research by Long and Shaw (2005) using data across the western states for ponderosa pine and the latest research by Long and Shaw (In review) for the Sierra Nevada Mixed conifer forests (Long, personal communication, Shaw, personal communication) suggest 450 as a maximum SDI for ponderosa pine and ponderosa pine dominated mixed conifer systems. Long and Shaw (In review) developed a density management diagram for even-aged mixed-conifer stands in the Sierra Nevada using 224 FIA plots in California. "The research is intended for use in even-aged stands, but may also be used for uneven-aged management where a large group selection system is used" (Long and Shaw In review). This research is directly applicable to the Keddie Ridge Project considering first-hand familiarity of the forests within the project area, the desired species composition, the desired low density conditions, and the relatively lower site of the project. This approach leans slightly toward maintaining higher stand densities than those using a maximum stand density index of 365 for ponderosa pine as described by DeMars and Barrett (1987) and Oliver (1995).

The stand-specific calculation of maximum stand density index for a mixed species stand is largely dependent on the relative abundance of species present. For mixed-species stands like those that occur within the Keddie Ridge Project, Tappenier et al. (2007) describes "several approaches have been recommended for establishing a maximum stand density. Cochran et al. (1994) recommend selecting the SDI of the species with the lowest maximum value, but Hann and Wang (1990) calculate a weighted average SDI in which the weights are the basal area of the respective species." These approaches are also described in Shaw (2006).

For the Keddie Ridge Project, a site-specific maximum stand density was calculated for each stand using the Forest Vegetation Simulator (FVS), which calculates maximum stand density weighted by the "proportion of basal area each individual species represents in the stand" (Dixon 2002) as described by Hann and Wang (1990). This may be a more appropriate measure of maximum stand density as it considers site-specific species composition reflected in the existing condition. While a maximum stand density index of 450 is used for ponderosa pine in this analysis, the individual stand maximum stand densities are higher – this is driven by the presence of shade tolerant species such as Douglas fir and white fir in these stands which have higher maximum stand density indices, This approach is well accepted as a component of the Forest Vegetation Simulator (Dixon 2002) and is consistent with 1) approaches described by the latest silviculture and ecology texts (Tappeneir et al. 2007), 2) the scientific literature (Hann and Wang 1990, Shaw 2006, Long and Shaw 2005, Long and Shaw In review)and 3) in collaboration with experts in the field of stand density (Long, personal communication, Shaw, personal communication).

10. **Basal areas and stand densities are based on even-aged ponderosa pine stand data: "There's no discussion, however, of what kind of heterogeneity from reference conditions might be desired or how it might be silviculturally implemented" (North comments on Keddie). We would like to see more specific treatments that outline how and where the prescriptions for the proposed action to meet desired conditions. Currently, it is difficult to interpret from the documents how heterogeneity will be implemented silviculturally both within stand (or micro-site) and on the landscape level. A particular area to focus some additional descriptions would be in the group selections. The DEIS (p. 73) states for group selections, "Harvest trees less than 30 inches DBH. Consider retaining healthy vigorous undamaged tress of desired shade intolerant species greater than 20 inches DBH…" and in the Forest Vegetation, Fire, Fuels, and Air Quality specialist report (pg. 110, g. i., ii., and iii). Neither document illustrates to reader the criteria that will be used for creating "clumps", "gaps", or low densities of larger trees. This was also mentioned during our phone conversation with Ryan Tompkins and Michael Donald on March 10th, and we were not satisfied with the conclusion that this would be more evident in the marking guidelines, which were not provided for review.** (Thomas et al., FL, pg. 11)

Response: Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report Appendix C, Alternative A, Diversity within the Prescription Design, Implementation of Landscape level heterogeneity, and Implementation of Within-stand level heterogeneity section. Tree selection guidelines and group selection guidelines discuss how heterogeneity would be implemented at the stand and landscape scales, including criteria that would be used for creating clumps, gaps, low densities of larger trees (the matrix), and identification, location, and design of group selections. Appendix C also includes a thorough discussion of how the design of alternative A implements the conceptual framework of the PSW GTR-200 (North et al. 2009). These guidelines were developed with input and review from Dr. North, lead author of the PSW GTR-220 (North et al. 2009).

11. **Using crown spacing is not supported by current research to mitigate uncharacteristic fire: On page 3 of the DEIS under Purpose 1: Reduce Hazardous Fuel Accumulations and Purpose 2: Improve Forest Health, the desired condition states, "… is uneven-aged management, multistoried, fire resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of fire." There are areas where reduction in canopy bulk density may be appropriate, in forests adjacent to homes or in areas for key strategic fire suppression activities to reduce fire severity under all weather scenarios, however, separating crowns outside of these key areas may be limited in its effectiveness to prevent crown fire spread (Agee et al. 2000, Stephens and Moghaddas 2005 in North et al. 2009 p. 3). Stephens and Moghaddas found using modeling tools Fuels Management Analysis (FMA) and Fire Family Plus software (with data supplied by specific inventories of trees size, shape, height and crown ratio) that, " [A]ll four outputs can be controlled by changing surface and ladder fuels, giving managers an opportunity to interactively develop target fuel conditions for a desired fire behavior. Fuels can be reduced until the crowning and torching indices are higher than conditions that are likely to occur even under extreme weather conditions." (In North et al. 2009 p. 3)** (Thomas et al., FL, pg. 12)

Response: Please refer to the FEIS, Chapter 1, Purpose 1: Reduce Hazardous fuel accumulations. The desired condition is an "uneven-aged, multistoried, fire-resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of crown fire." Also, please refer to the FEIS, Chapter 1, Purpose 2: Improve forest health. In addition to the fuels desired conditions, forest health desired conditions state that "stand densities would generally be low, characteristic of an active-fire stand structure, which would promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought, fire, and insect and disease occurrences."

The desired condition for forest health includes the desired condition for Purpose 1, Reducing Hazardous Fuel Accumulations, but in addition, includes promoting low stand densities, characteristic of an active-fire stand structure, which would promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought, fire, and insect and disease occurrence. In addition, low density, open canopy forest conditions would promote the regeneration, growth, and development of fire-resistant shade intolerant species such as ponderosa pine and black oak, and would contribute to landscape, stand, and within stand level heterogeneity. Removal of a portion of intermediate sized trees would contribute to creating low density, open canopy stands, accelerate the development of large diameter trees, reduce inter tree competition, enhance the growth and development of shade intolerant species, and contribute to heterogeneity.

Lastly for discussion regarding the need for fuel reduction, the basic components of fuel reduction, scale and intensity of fuel reduction, and the interaction of fuels reduction and forest health objectives and goals, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix B, Fuel Reduction section.

In addition, please see the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Effects Analysis Methodology section. Fire modeling software including Fire Family Plus, and the Fire and Fuels Extension of the Forest Vegetation Simulator with stand level tree field inventories were used in the analysis of effects by alternative.

12. **Using crown spacing is not supported by current research to mitigate uncharacteristic fire: There is substantial evidence indicating that it is not necessary to reduce canopy cover to 40 percent or to remove trees up to 30" dbh, as proposed in the Keddie project, to reduce the risk of uncharacteristic wildfire. Much of this evidence is cited in Legacy's appeal of the 2004 ROD, which was incorporated in our scoping comments on the Keddie project (SNFPC et al. 2004, pp. 62-71). It is generally recognized by fire scientists that fire resiliency largely is achieved by removing surface fuels and smaller diameter material and increasing crown to base height. "Most of the trees that need to be removed to reduce accumulated fuels are small in diameter and have little or no commercial value." (U.S. General Accounting Office 1999, p. 44). "When thinning is used for restoration purposes in dry forest types, removal of small diameter material is most likely to have a net remedial effect. Brush, small trees, along with fine dead fuels lying on top of the forest floor, constitutes the most rapidly ignited component of dry forest." (Christensen et al. 2002, p. 2). Thus, "surface fuels are the means by which crown fires are sustained....Without heavy surface fuels, crown fires are almost always absent, regardless of canopy cover, size class distribution, or the height to live crown." (Rice 2005, p. 2).** (Thomas et al., FL, pg. 12)

Response: Please refer to the response to comments FVFFAQ #11. In addition, please refer to the FEIS, Chapter 2, Alternatives section. The Keddie Ridge Project FEIS analyzes in detail four action alternatives which treat fuels to varying degrees. Alternative C, the non commercial funding alternative, is designed with the singular purpose of meeting the purpose and need for fuels reduction. This alternative would implement a substantially lower upper diameter limit of 12 inches dbh. Alternative D, the 2001 consistent alternative would implement lower upper diameter limits of 12 to 20 inches, would maintain higher amounts of canopy cover (50 percent), and would maintain 15 to 25 percent of the treatment area left untreated. Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality report, Appendix B, Fuels Reduction section. While these alternative would meet or partially meet immediate fuels reduction goals, it would not fully meet the forest health goals which include creating open forest stands that are generally low in stand density, characteristic of an active-fire regime stand structure, which would promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought fire, and insect and disease occurrences.

13. **Using crown spacing is not supported by current research to mitigate uncharacteristic fire: Studies of the effects of fuel treatments on fire behavior support the conclusion that fuel reduction that focuses on surface and ladder fuels and small diameter material is effective in reducing uncharacteristic fire. Stephens (1998) examined a number of fuel treatments and used the model FARSITE to evaluate their efficacy. In all cases, the most successful fuel treatments included prescribed fire. Further, prescribed fire alone was as effective in reducing fire risk as treatments with logging and prescribed fire combined. "These treatments resulted in fuel structures that will not produce extreme fire behavior at 95th percentile conditions." (Ibid. p. 32). Further, the vegetative conditions in the watershed where the fire effects were modeled included canopy cover conditions of up to 100 percent cover. The prescribed burning treatments did not reduce in any way the canopy cover of the dominant and co-dominant trees, yet these treatments were as effective as the thinning/biomass/prescribed burn treatments in which canopy cover was reduced to 50 percent in some areas of the watershed. Thus, no change in canopy cover of the dominant and co-dominant trees was necessary to meet the fuel objective under extreme weather conditions. Furthermore, reducing canopy in some areas to 50 percent did not result in any additional benefit. Similar results were reported by van Wagtendonk (1996), which again emphasized that removal of the surface and ladder fuels is effective in changing fire behavior. These studies demonstrate that it is not necessary to remove medium to large diameter trees or alter canopy cover in order to prevent crown fire and other extreme fire behaviors.** (Thomas et al., FL, pg. 12-13)

Response: Please refer to the response to comments FVFFAQ #11, #12, and #14. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality report, Appendix B, Fuels Reduction for a discussion on Scale and Intensity of fuels treatments. Research indicates that the effectiveness of fuels treatments is determined, in part, by the site specific existing stand conditions relative to the treatment prescribed. Research such as Moghaddas et al. (2010), Collins et al. (2010), Peterson et al. (2005) and Agee and Skinner (2005) all recognize prescribed fire, mechanical thinning, and mechanical thinning with prescribed fire as variable options for treating accumulations of hazardous fuels. Moghaddas et al. (2010) emphasize that "there is no one fuel treatment strategy…rather a combination of strategies is needed, especially when dealing with complex landscapes and management objectives (Stephens et al. 2010)." This is particularly important with regards to the multiple management objectives as described in the FEIS, Chapter 1, Purpose and Needs section. Treatments that may meet fuels reduction objectives, may not meet other project objectives such as forest health.

14. **Restoring fire as an ecological process need to be developed more within the specialist report: The DEIS and the Forest Vegetation, Fire, Fuels, and Air Quality specialist report both failed to identify the ecological restoration role that fire plays in this system, which furthers the underlying idea that thinning is always preferred.**

We understand that past management activities have lead to higher densities and species composition change, which is well summarized, "but the emphasis is on trying to restore ecological processes (including wildlife habitat) and those processes seem to thrive with greater structural

heterogeneity" (North comments on Keddie). The role that fire will play in the Keddie project in the now and into the future is unclear, and if the concepts from the GTR-220 are to be fully embraced we would like to see more discussion the tremendous ecological restoration value of fire (i.e., preparing the seedbed for germination, cycling nutrients and replenishing minerals, modifying conditions promoting wildlife habitat and forage, creating structural heterogeneity, minimizing disease and pathogens, and reducing or increasing fire hazard (Kilgore 1979).

"To completely restore fire as an ecological process, there is no substitute for fire. In the words of Sue Husari, fire management officer for the Pacific West Region of the National Park Service and one of the true pioneers in fire management: "You can't restore fire without fire."Sugihara et al. 2006. (Thomas et al., FL, pg. 13)

Response: Please refer to the response to comment FVFFAQ #11, #12, and #13. In addition, please refer to the FEIS, Chapter 2, Alternatives section . The Keddie Ridge Project recognizes the ecological role of fire in the project area, and consequently proposes thousands of acres of follow-up prescribed fire underburn treatments and prescribed burn only treatments,

All action alternatives include the use of prescribed fire to reduce surface fuels in the proposed treatments, including in all hand thinning and mechanical thinning treatments. In addition, all action alternatives include 1,456 acres of low to moderate intensity prescribed burn only treatments.

The commenters' "would like to see more discussion the tremendous ecological restoration value of fire (i.e., preparing the seedbed for germination, cycling nutrients and replenishing minerals, modifying conditions promoting wildlife habitat and forage, creating structural heterogeneity, minimizing disease and pathogens, and reducing or increasing fire hazard" (Kilgore 1979).

The reintroduction of fire as a process and the tremendous ecological value of fire is a fundamental component of the proposed treatments within all action alternatives as it is within guiding Forest Plan direction as amended by the 1999 HFQLG FEIS and ROD (USDA 1999) and the 2004 Sierra Nevada Forest Plan Amendment FEIS and ROD (USDA 2004a, USDA 2004b). This concept is the greatest similarity between all action alternatives, and consequently, the differences within the action alternatives lie in the amount and intensity of mechanical thinning and group selection treatments which would occur prior to the application of prescribed fire treatments. As North et al. (2009) highlights in the PSW GTR-220:

"Mechanical treatments can be effective tools to modify stand structure and influence subsequent fire severity and extent (Agee et al. 200, Agee and Skinner 2005) and are often a required treatment in forests containing excessive fuel loads. Prescribed fire is generally implemented very carefully, killing only the smaller size class trees (Kobziar et al. 2006). In some cases, it is ineffective for restoring resilience, at least in the first pass (Ritchie and Skinner 2007). For example, prescribed fire may not kill many of the larger ladder-fuel or co-dominant true fir trees that have grown in with fire suppression (Knapp and Keeley 2006, North et al. 2007). In many stands, mechanical thinning followed by prescribed fire may be necessary to achieve forest resilience much faster than with prescribed fire alone (Schwilk et al. 2009, Stephens et al. 2009)."

Consequently, the analysis in the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section focuses on how the relative differences in alternatives and how each alternative would or would not meet the desired conditions as described by the Purposes and Needs in the FEIS Chapter 1. In addition, the Forest Vegetation, Fuels, Fire, and Air Quality Report appendices include background information pertinent to the analysis. Appendix B includes a discussion on Fuel Reduction treatments including the need for fuels treatments, basic components of fuels treatments, scale and intensity of treatments, and the interaction of fuels reduction and forest health objectives and goals. Appendix C includes a thorough discussion on how alternatives would implement heterogeneity concepts as discussed in the PSW GTR-220 (North et al. 2009).

15. **Restoring fire as an ecological process need to be developed more within the specialist report: We also understand the complicated nature of air quality management, and if this were truly to be the collaborative approach alternative, then it would be very important to have the local air pollution control district at the table when discussing the Regions intentions to increase the pace and scale of ecologically based treatments (Ecological Leadership Intent) because the resilience and ecological integrity of the Sierran forests cannot be enhanced or maintained without managing fire within them.** (Thomas et al., FL, pg. 13)

Response: Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section for a discussion on effects to air quality. In addition, please see the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix B discussion on limitations to the use of prescribed fire. Implementation of prescribed fire treatments would occur over a range of years dependent on weather and fuels conditions being “within” prescription, air quality regulations, and available resources. Modifications to air quality regulations do not fall within the purview of the Keddie Ridge Project Collaboration with local air quality districts on air quality issues is addressed at the forest and regional level.

16. **To fully be able to call out a project that is using the GTR-220 concepts we would like to see the following revised in the DEIS and Forest Vegetation, Fire, Fuels, and Air Quality report. The following questions are for concepts that we do not see as being fully developed within the DEIS or within the specialist reports. A more fully developed section on stands and landscape level heterogeneity (see attach micro-site marking reference). How will the alternative A treatments and current prescriptions be varied across topographical and aspects differences within the stands. What criteria will you use to thin larger trees within CWHR 4 size classes, and how does this follow the concept in the GTR-220 of keying off existing structures? And how will this accelerate these stands into CWHR 4 is the larger trees are being removed? More detailed criteria on how the leave tree groups or clumps (both high and low density) and the creation of gaps will be established? The identification of these areas will help us understand more fully that the concepts of the GTR were in fact developed fully, and that this project falls in line with the Regions Ecological Restoration Intent. Furthermore, we would like to see more discussion on how fire will be returned to this project and be allowed to play it vital role in the ecosystem, both for reducing fuel loading and creating diversity.**

The above was also requested in our April, 2010 scoping letter, we requested that the district ensure stand heterogeneity be provided for in the project area in the following ways:

- **Varying stand density targets throughout the stand;**
- **Creating clumps composed of larger trees with higher density and canopy cover;**
- **Increasing stand density and canopy cover in canyons and north and northeast aspects;**
- **Retaining untreated areas ("diversity islands"); and**
- **Retaining patches of understory shrubs and advanced tree regeneration.**
- **Include specific wildlife tree microhabitat marking in the project design (Michel and Winter 2009) and procedures for identifying other micro-habitat features to be retained in project design.**

(SFL scoping letter for the Keddie Project, April 15, 2010, p. 2). The Keddie DEIS embraces a few concepts in the GTR such as heterogeneity, but only partially. The Forest Service should revise the DEIS to align the purpose and need, implementing the GTR, to include wildlife recommendations. (Thomas et al., FL, pg. 13, VI: Conclusion)

Response: Please refer to the FEIS, Chapter 2, Alternatives section, for the design of each alternative. Alternative A includes the greatest range in silvicultural prescriptions including the greatest ranges in canopy cover retention and stand density. This includes areas with higher densities, canopy cover, and retention of trees greater than 20 inches. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C for further discussion on implementing both landscape level, stand level, and within-stand level heterogeneity and how the design of Alternative A is congruent with the conceptual framework presented in the PSW GTR-220 (North et al. 2009). In addition, the Keddie Ridge Project ID team has worked with the lead author of the PSW GTR-220, Dr. Malcolm North, to incorporate the report's conceptual framework into the Keddie Ridge Project as appropriate.

17. **No rational connection between the facts found and the proposed action: The DEIS claims that the Proposed Action is necessary in order to prevent high levels of tree mortality from various causes, including fire and insects. However, the facts found in the Forest Service's own Forest Vegetation Simulator (FVS) data, pertaining to the Project area, present irreconcilable contradictions. First, there is no information in the record indicating that stands will not continue to increase in live tree basal area over the coming decades, even when beetle mortality is taken into account. Also, about 25 percent basal area mortality levels identified in the DEIS and Keddie Forest Vegetation, Fuels, Fire, and Air Quality Report (Vegetation Report) would be from the logging itself—i.e., the direct killing and removal of trees with chainsaws, with an additional 13 percent basal area mortality projected from fire under the most extreme fire weather—a total of 38 percent basal area mortality. HOWEVER, under the non-commercial thin (thinning of trees up to 12 inches in diameter removed) the combined live basal area reduction from thinning and fire (under "extreme" fire conditions) is much smaller than**

> **combined mortality under the Proposed Action—i.e., basal area mortality of only 15 percent from thinning and basal area mortality of only 13 percent from fire under extreme fire weather (a total of only 28 percent mortality). Thus, there is a fundamental disconnect in the DEIS between the facts found and the proposed decision, especially in light of the data discussed in the section below about the low levels of beetle mortality generally associated with high levels of basal area and stand density index.** (Chad Hanson, JMP, pg. 1)

Response: Please refer to the FEIS, Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Forest health desired conditions include creating open canopy stands of large fire resistant trees that are generally low in stand density, characteristic of an active-fire stand structure, to promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought, fire, and insect and disease occurrence.

Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Analysis Methodology, Measurement indicators for Forest Vegetation, Fuels, and Potential Fire Behavior and Effects section. These measurement indicators focus on residual, post-treatment attributes of forest vegetation structure, density, species composition, and landscape diversity and heterogeneity as residual post-treatment conditions are the best indicator of how well desired conditions as described in Chapter 1 would be met for the project purposes and needs. Simply put, measures that display what remains after treatment best describe whether desired conditions are met; the measure of how much basal area is removed offers little context with regards to desired conditions.

Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Environmental Consequences, Comparison of Effects by Alternatives, Direct and Indirect Effects: Mechanical Thinning Treatments & Cumulative Effects section for a discussion comparing how well each alternative meets the purposes and needs of the project. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A for a discussion on the low density and open canopy nature of desired conditions, and Appendix B for discussion on scale and intensity of fuel treatments and the interaction between fuel treatments and forest health objectives. In general, proposed mechanical treatments under alternatives A and E would remove more trees, canopy cover, and basal area than alternatives C and D, and would better enhance landscape, stand level, and within-stand heterogeneity. While the commenter recognizes that alternative A would mechanically remove more trees relative to alternative C, the comment fails to account that prescribed fire treatments would create more residual mortality in the form of leaving more dead standing trees which would then contribute to future hazardous fuel loads. This effect and the subsequent management considerations are discussed in the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix B, Scale and Intensity of Treatment, and Interaction of Fuels and Forest Health Objectives sections.

In addition, the commenter is inappropriately using percent basal area mortality as a measurement indicator. Predicted percent (basal area) mortality is the potential tree mortality as measured by the percent of basal area that would be killed in a fire event occurring under 90th percentile weather conditions as predicted by FFE (Reinhardt and Crookston 2003, Rebain et al. 2010); this is not the percent basal area mortality that would occur as the result of the proposed treatments.

Lastly, the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality , Environmental Consequences, Alternative B section, acknowledges that stand growth would continue under the no-action alternative. In these forested systems, net stand growth would likely outpace mortality; however, this does not mean that there isn't an increased potential and susceptibility of these forests to unacceptable levels of mortality. It is well documented in the scientific literature, and the Keddie Ridge Project Forest Health Evaluation that as stand density increases the risk and susceptibility of these forests to unacceptable levels of mortality due to drought, insects, and disease, also increases. Consequently, indicator measures of stand density are used to characterize forest health risks and how this corresponds with the proposed treatments for each alternative. The FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Affected Environment and Environmental Consequences, Alternative B and the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A, Stand density, existing condition of Forest health, and climate change sections all discuss the negative environmental consequences associated with high density stands which has been well documented in the scientific literature.

18. **No rational connection between the facts found and the proposed action: Moreover, the Keddie Forest Vegetation, Fuels, Fire, and Air Quality Report (pp. 49-50) claims that the non-commercial alternative, Alt. C, would leave basal area and stand density index levels that would "NOT" be "within desired conditions" (emphasis in original). Yet, the desired conditions described in the Purpose and Need section of the DEIS make no mention of specific thresholds for basal area or stand density index that must be met; nor does the DEIS explain in any meaningful way the supposed negative consequences that are sought to be avoided by reducing stand density and basal area to the levels in the Proposed Action. Instead, the DEIS merely makes vague references to the potential for some amount of beetle mortality—i.e., future snag recruitment above zero—but does not quantify this expected mortality relative to the mortality that would result from the logging itself.** (Chad Hanson, JMP, pp. 1-2)

Response: Please refer to the FEIS, Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators for a discussion of basal area and stand density use, relevant thresholds, and desired conditions. As FVFFAQ #21 and #24 discusses, these measurement indicators are used to display how well alternatives would meet forest health conditions. These measurement indicators and corresponding thresholds have been widely used in scientific literature to display susceptibility of stands to mortality from the combination of drought and bark beetles, and effectively characterizes the risk in these conditions post-treatment for each alternative.

In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion regarding background information, management guidelines, and scientific literature on basal area and stand density and their relation to improving forest health. The FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Environmental Consequences, Alternative B for the negative consequences "that are sought to be avoided by reducing stand density and basal area to the levels in the proposed action."

19. **Failure to divulge methodology, and inaccuracies, regarding stand density and stand density index (SDI): First, the DEIS states that stands would be thinned such that their SDI (stand density index) would be no more than 60 percent of limiting or maximum SDI even 20 years after thinning, BUT fails to identify the scientific source or rationale for reducing stand density so severely that stands would still be less than 60 percent of LIMITING SDI at 20 years post-thinning, or provide any rationale or methodology to explain the levels of tree mortality that would likely occur, based upon the scientific data, if stands exceed 60 percent of the chosen SDI threshold/target, relative to the level of tree mortality expected due to cutting and removal of trees with chainsaws under the Project.** (Chad Hanson, JMP, pg. 2)

Response: Please refer to the FEIS Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Forest health desired conditions include creating open canopy stands of large fire resistant trees that are generally low in stand density, characteristic of an active-fire stand structure, to promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency.

Relative density as described in the FEIS Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators, is used as a measurement indicator to compare how well proposed treatments and corresponding silvicultural treatments for all action alternatives would meet desired conditions for forest health, including how well these proposed treatments meet guidance for thinning treatments developed by Region 5 (Blackwell 2004, Landram 2004). The calculation of relative density is based on the maximum stand density index and is described in the FEIS and the Forest Vegetation, Fuels, Fire, and Air Quality report Appendix A. This is consistent with current research definition and application of stand density index (Shaw and Long 2010).

The Forest Vegetation, Fuels, Fire, and Air Quality report Appendix A provides discussion on reference conditions and appropriate stand density levels for stands characteristic of an active-fire stand structure. In addition, Blackwell (2004) provides guidance advising forest managers to develop thinning prescriptions to ensure that stand densities do not exceed an upper limit, for example 60 percent of maximum stand density index, for at least 20 years after thinning. Blackwell (2004) based this recommendation on the increasing incidence of both tree mortality and large fire occurrence in California National Forests which have been subsequently been documented in scientific literature (Miller et al. 2009). The intent was to avoid situations where projects only treat surface and ladder fuels to meet short term fuels objectives while not addressing long term forest health risks. These recommendations are consistent with the latest research on fuels reduction and ecosystem restoration for forested systems of the Sierra Nevada mixed conifer forests (Collins et al. 2011) which suggest that treatment prescriptions that maintain higher densities, maintain high canopy covers, and implement lower diameter limits "may be too conservative with respect to residual stand structure" and "are on the upper end of or entirely exceed the values we report in distributions based on the 1911 data (Fig 3.)"(Collins et al. 2011).

Lastly, please refer to the FEIS, Chapter 2, Alternatives. Under the proposed action, proposed treatments and corresponding silvicultural prescriptions are designed and developed using canopy cover, CWHR type, and upper diameter limits to fully meet the desired conditions as described in the FEIS Chapter 1. All proposed treatments would meet standards and guidelines as directed in the 2004 SNFPA ROD, table 2 (USDA 2004b).

For responses to related stand density topics, please refer to response to comments FVFFAQ #4, #6, #7, #8, #9, #21, and #24.

20. **Failure to divulge methodology, and inaccuracies, regarding stand density and stand density index (SDI): Second, the Vegetation Report (p. 10) cites Oliver (1995), vaguely asserts that beetle mortality occurs above a basal area of 150. However, in the ponderosa pine plots in California within natural forest stands (i.e., not plantations), the densest plots increased to basal areas well over 200 square feet per acre with almost no beetle mortality (i.e., mortality of trees from beetles) after the stands reached about 85 years of age (Oliver 2005, Fig. 1). The stands in the Project area are natural forests over 85 years of age. Oliver (2005) noted that mortality levels have "declined over the years" in the eastside ponderosa pine forests as these forests have grown older and denser. Oliver (2005 [Fig. 1]) found that basal area mortality was minor in ponderosa pine stands above 150 square feet per acre—about 5-15 percent basal area mortality every 10-30 years, while stands gently increased in live tree basal over time.** (Chad Hanson, JMP, pg. 2)

Response: Please refer to the FEIS Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators for a discussion of basal area and stand density use, relevant thresholds, and desired conditions. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion regarding background information, management guidelines, and scientific literature on basal area and stand density and their relation to improving forest health.

Oliver (1995) concludes that "Sartwell's threshold of 34 m^2 per ha (150 ft^2 per acre) of basal area above which density stands are susceptible to attack by bark beetles appears to be a reasonable average value for California." In addition, basal area per acre has also been used by Landram (2004) to develop insect risk thinning guidelines for the eastside, transition, and westside zones of the Plumas National Forest. For the transition zone (where the Keddie Ridge Project is located), the insect risk thinning guidelines suggest thinning to 150 square feet per acre. These recommendations are consistent with Oliver (2005) who concludes that a primary example of a satellite study of the west wide levels of Growth study in ponderosa pine has demonstrated "the efficacy of low reserve densities in maintaining stand health…Because, most tree mortality whether it is caused by biotic or abiotic factors, is episodic, evaluations of forest health are meaningful only if reserve densities are maintained over a long period of time."

Oliver (2005, Figure 1) does not show as the commenter asserts that "the densest plots increased to basal areas well over 200 square feet per acre with almost no beetle mortality (i.e., mortality of trees from beetles) after the stands reached about 85 years of age" nor does it show that Oliver "found that basal area mortality was minor in ponderosa pine stands above 150 square feet per acre." Contrary to these assertions, Oliver (2005) acknowledges that mortality occurred primarily in plots that had higher reserve densities (p. 75).

The theme of low stand densities in maintaining forest health and improving forest resiliency to disturbances such as drought, insect and disease, and fire, is common among literature describing reference conditions of active-fire stand structure, forest health management, and climate change recommendations. Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion.

For responses to related stand density topics, please refer to response to comments FVFFAQ #4, #6, #7, #8, #9, and #19.

21. **Failure to divulge methodology, and inaccuracies, regarding stand density and stand density index (SDI): Third, the Vegetation Report (p. 5) acknowledges that the Project area is comprised of mixed-conifer and true fir, not pure ponderosa pine stands, and states that the maximum stand density index (SDI-Max) for mixed-conifer forests is 750 (Vegetation Report, p. 11). The Vegetation Report (pp. 10-11) implies that significant beetle mortality occurs at stand density index (SDI) levels above 55-60 percent of the maximum SDI. However, the Vegetation Report utterly fails to describe the actual level of basal area mortality that can be expected above 60 percent of SDI-Max, and the cited studies on pp. 10-11 of the Vegetation Report do not indicate that basal area mortality from insects when stands exceed 60 percent of the SDI-Max of 750 (i.e., when they exceed an SDI of 450) will exceed the mortality levels from logging itself projected under the Proposed Action.** (Chad Hanson, JMP, pg. 2)

Response: Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators for a discussion of stand density use, relevant thresholds, and desired conditions. The FEIS states that "Reinecke (1933) described a maximum stand density of 750 for mixed conifer stands in California." However, goes on to explain that the calculation of this maximum stand density is largely dependent on the mix of species. The Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density further explains that for mixed-species stands like those that occur within the Keddie Ridge Project, Tappenier et al. (2007) describes "several approaches have been recommended for establishing a maximum stand density. Cochran et al. (1994) recommend selecting the SDI of the species with the lowest maximum value, but Hann and Wang (1990) calculate a weighted average SDI in which the weights are the basal area of the respective species." These approaches are also described in Shaw (2006).

A more site-specific maximum stand density was calculated for each stand using the Forest Vegetation Simulator (FVS) which calculates maximum stand density weighted by the "proportion of basal area each individual species represents in the stand" (Dixon 2002). This may be a more appropriate measure of maximum stand density as it considers site-specific species composition reflected in the existing condition. For, the purpose of this analysis, relative density based on the maximum stand density index as calculated by FVS is used for each individual stand.

In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion regarding background information, management guidelines, risk for beetle induced mortality, and scientific literature on basal area and stand density and their relation to improving forest health. "Actual levels of basal area mortality that can be expected above 60%" relative density is difficult to quantify due to the limitations of forest growth and yield model (FVS) in simulating insect outbreaks and predicting periods of drought. However, FVS does provide meaningful estimates of stand density and basal area, measures which have been widely used in forest management and scientific literature as indicators of or thresholds of elevated risk for these forest health issues (Powell 1999, Ferrell 1993, Sartwell 1971, Sartwell and Stevens 1975, Oliver 1995, Oliver et al. 1996, Landram 2004, Negron and Popp 2004, Negron et al. 2009). Consequently, the FEIS displays how well each alternative meets these indicators or thresholds which describe elevated risk of bark beetle mortality and display how susceptible forested stands may be to these forest health concerns.

Please refer to the FEIS Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Under the proposed action, proposed treatments and corresponding silvicultural prescriptions are designed and developed using canopy cover, CWHR type, and upper diameter limits to fully meet the desired conditions as described in the FEIS Chapter 1. Relative density as described in the FEIS Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators, is used as a measurement indicator to compare how well proposed treatments and corresponding silvicultural treatments for all action alternatives would meet desired conditions for forest health, including how well these proposed treatments meet guidance developed by Region 5 (Blackwell 2004, Landram 2004).

For responses to related stand density topics, please refer to response to comments FVFFAQ #4, #6, #7, #8, #9, #19, #20, and #24.

22. **Failure to divulge methodology, and inaccuracies, regarding stand density and stand density index (SDI): Fourth, the Vegetation Report (p. 11) states that the maximum SDI—i.e., the SDI level used to determine the target SDI percentages—is 750 for mixed-conifer forests like those in the Project Area, as discussed above. However, the FVS outputs for the Keddie Project show that the Forest Service is actually using a much lower SDI-Max value that is has neither**

disclosed nor supported with any scientific data. For example, under Prescription 1 in the FVS Outputs, 40 percent of maximum SDI is listed as 231 in one case, and 39 percent of maximum is listed as 251 in another. In other cases, 46 percent of maximum is listed as 264 and 44 percent of maximum is listed as 297. Whatever methodology was used to derive the maximum and the percentages of maximum, they were not adequately discussed, divulged, or supported with evidence in the DEIS or Vegetation Report. Moreover, as discussed above, the Vegetation Report (p. 11) makes false statements, implying that, because SDI-Max is 750, far higher SDI levels (i.e., far more trees) would be retained than would actually result under the Proposed Action. (Chad Hanson, JMP, pg. 3)

Response: Please refer to response to comment #21. Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators, and the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for a discussion of background information, scientific literature, methodology for calculating site-specific maximum stand density.

A site-specific maximum stand density was calculated for each stand using the Forest Vegetation Simulator (FVS) which calculates maximum stand density weighted by the "proportion of basal area each individual species represents in the stand" (Dixon 2002). This may be a more appropriate measure of maximum stand density as it considers site-specific species composition reflected in the existing condition.

In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion regarding detailed background information, methodology and consistency with scientific literature, and management guidelines on stand density and its relation to reference conditions, climate change, existing conditions, and improving forest health.

For responses to related stand density topics, please refer to response to comments FVFFAQ #4, #6, #7, #8, #9, #19, #20, and #21.

23. **Scientific Accuracy and Integrity, Generally: The DEIS implies that stands in the Project Area exceed some desired percentage of the maximum stand density index for ponderosa pine-dominated stands. The DEIS fails to include any citations to scientific studies to support the statement about what the maximum stand density index is, or to support the DEIS's contention that it is ecologically desirable and beneficial for forest wildlife species and biodiversity to reduce stand density below some threshold percentage, and further reduce large snag densities in the future.** (Chad Hanson, JMP, pg. 3)

Response: Please refer to the FEIS, Chapter 1, Purpose and Needs, Purpose 2: Improve Forest Health for a discussion of objectives, the need for action, desired conditions, and measures of modifying forest structure and species composition. Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality section, Effects Analysis Methodology, Measurement Indicators for a discussion of basal area and stand density use, relevant thresholds, and desired conditions. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix A: Stand Density, Reference Conditions, Existing Conditions of Forest Health, Climate Change, and Desired Conditions for further discussion regarding background information, management guidelines, and scientific literature on basal area and stand density and their relation to improving forest health. For responses to related stand density topics, please refer to response to comments FVFFAQ #4, #6, #7, #8, #9, #19, #20, #21, and #22.

For responses related to stand density and its relation to snags and large down woody debris retention and recruitment, please refer to response to comments #3 and #8. Please refer to the FEIS, Chapter 2, Alternatives, Tables 5, 6, and 7 for design criteria for snag retention and residual surface fuels (including large down woody debris). In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report, Appendix C, Implementation of heterogeneity and Tree Selection guidelines items #5 "Damaged, "Defect" and Wildlife Retention Trees, and #7 Snag Retention guidelines. These guidelines provide further direction on 1) retaining trees that serve as suitable wildlife habitat structures, 2) snag retention and recruitment, and 3) large down woody debris retention and recruitment.

24. **Scientific Accuracy and Integrity, Generally: The DEIS fails to provide information about the number, or basal area, of trees that would be removed through mechanical thinning relative to the number/basal-area that would be expected to die due to competition mortality as SDI increases, e.g., as predicted by Oliver (1995); and the DEIS fails to explain why mortality of trees through chainsaws and removal to timber mills is "restoration" and "forest health" enhancement, while natural mortality of a similar (or lower) number of trees through competition, and resulting creation/recruitment of ecologically-important snags for cavity-nesting wildlife, would somehow be ecologically harmful.** (Chad Hanson, JMP, pg. 3)

Response: Please refer to the FEIS, Appendix A, tables 2, 4, 6, and 8 for number of trees, basal area, and canopy cover before and after treatments. In addition, during the comment period, FVS outputs for each stand and prescription were provided showing number of trees per acre by diameter class and basal area per acre, both before and after treatments. Lastly the FEIS, Appendix D, Economic Analysis provides a relative estimate of volume of harvested trees by species both greater than 24 inches in diameter and less than 24 inches in diameter by alternative. These data display the existing condition and stand attributes and post-treatment condition and stand attributes and also show, by default, umber and basal area of trees to be harvested and removed. However, breakdown of number of trees or basal area of trees removed are a poor indicator of whether a) desired conditions, b) concepts within the GTR are met, or c) environmental effects to forest vegetation, fuels, and fire behavior, because this focuses on what is being *removed*, not what conditions *remain* after the treatment. Comparisons of Pre-treatment and Post-treatment stand conditions are far more applicable to how well desired conditions are met.

Please refer to the FEIS, Chapter 1, Purpose and Need for desired conditions for fuels reduction and forest health. This section describes the need for action to reduce hazardous fuel accumulations, improve forest health, protect and enhance habitat for Region 5 Forest Service sensitive plant and wildlife species, improve watershed health, and reduce noxious weed infestations. Under the Proposed Action, proposed treatments were designed to fully meet these purpose and needs. Please refer to the FEIS Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Measurement Indicators and Environmental Consequences including comparison of alternatives for a discussion on the measurement indicators used to analyze alternatives effects and effectiveness in meeting desired conditions in terms of forest structure and composition, landscape heterogeneity, and fuels and fire behavior. In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality report, Appendices A and C for existing pre-treatment and residual post-treatment conditions with regards to the measurement indicators. The FEIS Appendix A, tables 2, 4, 6, and 8 also displays more unit specific post treatment stand conditions and ranges in conditions after treatment for each alternative.

The FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality, Affected Environment and Environmental Consequences, Alternative B discusses the environmental effects of allowing " natural mortality through competition". Furthermore, this The FEIS discusses that by maintaining high stand densities and allowing natural mortality through competition, stands are at higher risk to large scale mortality from insect and disease outbreaks which may be exacerbated by periods of drought. This is well documented in past the scientific literature (Guarin and Taylor 2005, Macomber and Woodcock 1994, Fettig et al. 2007, Ferrell 1993,Ferrell 1996, Powell 1999, Egan et al 2010). In addition, the Forest Vegetation, Fuels, Fire, and Air Quality report Appendix A further discusses how these trends have the potential to intensify with climate change and affect valuable landscape attributes such as large diameter trees (Battles 2008, Lutz et al. 2009). The Keddie Ridge Project specific Forest Health evaluation (Cluck and Woodruff 2010) recognizes that stands within the project "are at a high risk to bark beetle caused tree mortality due to overstocked conditions and could experience unacceptable levels of tree mortality in the future." Once these beetle and/or disease outbreaks begin, management options to control such outbreaks are limited, especially when exacerbated by periods of drought. It is also well documented in the scientific literature (Ferrell 1996, Fettig et al 2007, Egan et al. 2010) that the most effective methods to reduce risk of unacceptable levels of tree mortality is through preventative silvicultural techniques, particularly thinning to reduce stand density.

Consequently allowing natural mortality through competition would not meet the project purposes and needs for action and would leave the landscape susceptible to mortality caused by drought, insects, disease, and fire.

In addition, please refer to response to comments FVFFAQ #3, #8, and #24 for additional discussion on snag and large down woody debris retention and recruitment.

25. **Effect of stand density reduction on future large snag levels and Wildlife, B. Effects and cumulative effects of targeting dense mature stands: Further, the HFGLG Final EIS (QLG FEIS) states on page 3-58 that the eastside forests of the QLG project area are seriously deficient in dense, mature and old growth forest habitat, and have too many openings relative to historic times. As such, the QLG FEIS states for eastside forests:**

"Due to the existing condition, it is probable that stands having mid-seral size class and density attributes (seral stages…H-3B/C, H-4A) would be adversely impacted by group selection because

these areas would be targeted for treatment and not protected by interim direction for California spotted owl. In addition to changes to the tree size class attribute of mid-seral to late-seral stands is the effect of openings. In contrast to the west slope of the planning areas, mid-seral and uneven-aged eastside mixed conifer and pine stands have far more and larger anthropogenic openings (wildfire burns, regeneration cuts, roads, skid trails, landings) today than those cause by adaphic [sic] and stochastic factors (rock outcrops, insect patches, patch burns, windthrow) in the past. As eastside fir and mixed conifer mid-seral stands increase their late-seral values the creation of more openings and removal of the larger trees would increase earlier seral attributes creating a further imbalance in the quantity of land now occupied by the various seral stages. As for eastside pine, thinning would promote later seral values, but group selection would reverse the trend for mid-seral stands."

Seral stage H-3B/C is defined as having trees 12-23.9 inches in diameter and canopy cover of more than 40 percent (with H-3C being the highest canopy cover). Plumas Forest Plan, Appendix E, pp. 1-2. Seral stage H-3B/C is equivalent to CWHR 4M and 4D. In other words, there are now more openings and more open forests on the eastside of the northern Sierra Nevada than there were historically, and fewer dense, old forests. This is a special concern, given the fact that the Project appears to target dense, old stands. These dense, mature forest areas are the areas that are capable of producing (recruiting) large snags through competition between trees. If such habitat areas are already in deficit on the eastside, as the QLG FEIS states, then the Project would have significant adverse cumulative effects—i.e., cumulative effects on native wildlife species dependent upon high densities of large snags within green forests. (Chad Hanson, JMP, , pg. 4)

Response: Please refer to the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality Section, Introduction. The Keddie Ridge Project is not located in the "eastside forests of the QLG project area". The Keddie Ridge Project is located primarily in the transition zone – an ecological zone used to describe the transition between the wet productive westside forests of the Sierra Nevada and the relatively dry, less productive eastside forests of the Sierra Nevada as described by the HFQLG FEIS (USDA 1999).

Furthermore, the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality Section, Affected Environment displays that the majority of NFS lands within the analysis area for Forest Vegetation, Fuels, Fire, and Air Quality are mid-seral closed canopy stands characterized by CWHR 4M and 4D. The affected environment described the high density and homogenous nature of these stands. Because such stand structure has increased vulnerability to high-severity fires, insect outbreak, and landscape level drought-induced mortality, a homogenous occurrence of this seral stage across the landscape is unstable (McKelvey and Johnston 1992, Millar et al. 2007). A more diverse distribution of seral stages, characterized by heterogeneous stand structures, may be more resilient to disturbance events such as fire, drought, and insect and disease infestations and more characteristic of desired conditions (Stephens and Fule 2005, Millar et al. 2007, Collins and Stephens 2010).

Please refer to the FEIS, Chapter 3, Environmental Consequences, Cumulative Effects and Comparison of Alternatives, for a discussion on how proposed alternatives and corresponding treatments may affect landscape level heterogeneity with regards to seral stages as represented by CWHR size class and density. Proposed treatments under alternatives A and E would convert mid-seral canopy stands (CWHR 4M and 4D) stands into open canopy stands (CWHR 4P) and create conditions that reduce inter tree competition and accelerate the growth and development of large diameter trees. This would enhance heterogeneity at the landscape and stand levels and promote the development of later seral open canopy stands as described in the desired conditions for forest health.

In addition, please refer to response to comments FVFFAQ #3, #8, and #24 for additional discussion on snag and large down woody debris retention and recruitment.

26. **Misrepresentation of fire effects and failure to discuss the ecological importance of mixed-intensity fire: The DEIS fails to adequately discuss the fact that, historically, there was always some mix in fire intensities in the forests of the northern Sierra Nevada and eastside Cascades, and high-intensity fire patches were both common and natural (Beaty and Taylor 2001, Bekker and Taylor 2001, Hessburg et al. 2007, Bekker and Taylor 2010). Bekker and Taylor (2010) found that, in an unmanaged area of the Lassen National Forest within mixed-conifer forests, the fires burned mostly at high-intensity historically, with some high-intensity fire patches being thousands of acres in size. Bekker and Taylor (2010) concluded that "high-severity fire was important in shaping stand structure" historically. Further, the Project documents fail to discuss the fact that patches of high-intensity fire support very high levels of native biodiversity and many wildlife species depend upon such habitat (Hutto 1995, Hutto 2006, Noss et al. 2006, Hanson 2010, Swanson et al. 2010). The DEIS describes fire intensities other than low intensity as being wholly negative for the forest ecosystem and the wildlife species that inhabit it, and this is inaccurate.** (Chad Hanson, JMP, pp. 4-5)

Response: Please refer to the FEIS, Chapter 1, Purpose and Need, Purpose 1 Reducing Hazardous Fuel Accumulation. The objective is to modify fire behavior by reducing hazardous fuels to protect communities, fire fighters, and biological resources. The FEIS, Chapter 1, Purpose and Need, Background provides a recent and local example of how high severity wildfire has impacted biological resources, and the Purpose and Need 1 discuss the need for action. The desired condition is an uneven-aged multistoried, fire-resilient forest of open forest stands dominated by large fire-tolerant trees with crowns sufficiently spaced to limit the spread of crown fire.

In addition please refer to the FEIS, Chapter 2, Alternatives considered but eliminated from detailed study, Alternative F. The 2004 SNFPA ROD does not include the incorporation of high severity effects within prescribed fire treatments.

In addition, please refer to the Forest Vegetation, Fuels, Fire, and Air Quality Report Appendix B, Fuels Reduction, Need for Fuels Reduction. Many studies such as Bekker and Taylor (2001), Beaty and Taylor (2001), and Hessburg et al. (2007), Miller et al. (2009), and Collins and Stephens (2010) have discussed the occurrence of moderate, high, and mixed severity occurrences within dry mixed conifer forests of the Cascades and Sierra Nevada ranges. However, Fire Regime data for the Keddie Ridge Project area indicates that over 96 percent of stands proposed for treatment within the Keddie Ridge Project fall within Fire Regime I, a fire regime characterized by frequent primarily low to mixed severity fire.

Concerning high severity patch sizes, recent large wildfires are very different from presettlement fires with respect to the average sizes of patches of high severity fire within the fire perimeter. High severity patches more than a few acres in size were unusual in fires in the Sierra Nevada before Euroamerican settlement (Show and Kotok 1924, Kilgore 1973, Stephenson et al 1991, Weatherspoon et al. 1992, Skinner 1995, Skinner and Chang 1996, Weatherspoon and Skinner 1996, Safford 2007, Safford pers. comm. 2008a, Safford 2008b). Miller et al. (2008) have also shown trends indicating that the average size of high severity patches in Sierra Nevada wildfires has increased (by about 100 percent) over the last 25 years (Safford pers. comm.. 2008a, Safford 2008b).

While the occurrence of fire (including low, moderate, and high severity fire) on the landscape is a natural disturbance that is essential to ecosystem function, the large scale of these fires, particularly the vast proportion that burned under high severity, are well outside the natural range of variability in fire size and severity experienced on the Plumas National Forest in the past and are uncharacteristic of the "natural" fire regimes typically described for the dry Sierra Nevada forests (Peterson et al 2009, Miller 2008, Safford 2007, Safford et al. 2007, Safford 2008b, Stephens et al 2007, Beaty and Taylor 2007, Moody and Stephens 2002, , Gruell 2001, McKelvey et al. 1996, Weatherspoon 1996, Weatherspoon and Skinner 1996, Skinner and Chang 1996, McKelvey and Johnston 1992, Leiberg 1902,).

As stated above, for the purposes of the Keddie Ridge Project, fuels treatments are designed to modify fire behavior by reducing hazardous fuels to protect communities, fire fighters, and biological resources and to create open forest conditions where fire severity is reduced. The FEIS, Chapter 3 Forest Vegetation, Fuels, Fire, and Air Quality Section, Affected Environment shows that within the Keddie Ridge Project, forested stands are highly vulnerable to the effects of uncharacteristically severe wildfire – over 70 percent of NFS lands within the analysis area have a high departure from the natural regime and predispose the system to high risk of loss of key ecosystem components.

27. The DEIS fails to explain why, for fire and fuels purposes, it proposes to remove many mature fire-resistant trees up to 20 or 30 inches in diameter. Contrary to the implication of the DEIS, removal of intermediate-sized trees is unnecessary where the purpose is to effectively reduce the potential for severe fire. Recent scientific studies have found that precommercial thinning of sapling and pole-sized trees only (up to 8-10 inches in diameter) effectively reduces fire severity. See, for example:

   a. Omi, P.N., and E.J. Martinson. 2002. Effects of fuels treatment on wildfire severity. Final report. Joint Fire Science Program Governing Board, Western Forest Fire Research Center, Colorado State University, Fort Collins, CO. Available from http://www.cnr.colostate.edu/frws/research/westfire/finalreport.pdf (found that precommercial thinning of trees under 8 to 10 inches in diameter reduced potential for severe fire (email communication with the authors confirmed that trees removed were of this small size class)). More specifically, the Omi and Martinson (2002) study, found that

precommercial thinning reduced stand damage (a measure of fire severity generally related to stand mortality) in both of the two thinned study sites, Cerro Grande and Hi Meadow (the authors reported that the Hi Meadow site was marginally significant, p<.1, perhaps due to small sample size), each with several plots.

b. **Martinson, E.J., and P.N. Omi. 2003. Performance of fuel treatments subjected to wildfires. USDA Forest Service Proceedings RMRS-P-29 (found that non-commercial thinning of submerchantable-sized trees, generally followed by slash burning or removal, in several areas across the western U.S. greatly reduced fire severity, and that this result held true regardless of post-thinning basal area density).**

c. **Strom, B.A., and P.Z. Fule. 2007. Pre-wildfire fuel treatments affect long-term ponderosa pine forest dynamics. International Journal of Wildland Fire 16: 128-138 (non-commercial thinning of very small trees under 20 cm dbh (8 inches dbh) in seven different sites dramatically reduced fire severity, resulting in post-fire basal area mortality of only about 28 percent (low severity) in non-commercially thinned areas versus post-fire basal area mortality of about 86 percent in untreated areas).** (Chad Hanson, JMP, , pp. 6-7, Thinning and Fire Severity)

Response: Please refer to the response to comments FVFFAQ #11 and #12. In addition, please refer to the FEIS, Chapter 2, Alternatives. The Keddie Ridge Project FEIS analyzes in detail four action alternatives which treat fuels to varying degrees. Alternative C, the non commercial funding alternative, is designed with the singular purpose of meeting the purpose and need for fuels reduction. This alternative would implement a substantially lower upper diameter limit of 12 inches dbh and consequently would implement treatments similar to those described by literature and cited by the commenter. Alternative D, the 2001 compliant alternative, would implement lower upper diameter limits of 12 to 20 inches, would maintain higher amounts of canopy cover (50 percent), and would maintain 15 to 25 percent of the treatment area left untreated. In addition, nearly half of the acres proposed for treatment in all action alternatives include prescribed fire only or hand thinning treatments described by literature and cited by the commenter; However, alternatives A and E also propose a wider range and diversity of treatment intensities.

Please refer to the Forest Vegetation, Fuels, Fire, and Air Quality report, Appendix B, Fuels reduction. While these alternatives would meet or partially meet immediate fuels reduction goals, alternatives C and D would only and uniformly implement low intensity thinning treatments that would not fully meet the forest health goals. Forest health desired conditions include creating open forest stands that are generally low in stand density, characteristic of an active-fire regime stand structure, which would promote the growth and development of large diameter trees, reduce inter-tree competition, and improve forest resiliency to drought fire, and insect and disease occurrences. Please refer to the FEIS, Chapter 2, Comparison of alternatives, and the FEIS, Chapter 3, Forest Vegetation, Fuels, Fire, and Air Quality Section, Environmental Consequences, Comparison of Alternatives. The lower intensity treatments proposed under alternatives C and D do not meet desired conditions described for forest health.

Moghaddas et al. (2010) emphasize that “there is no one fuel treatment strategy…rather a combination of strategies is needed, especially when dealing with complex landscapes and management objectives (Stephens et al. 2010).” This is particularly important with regards to the multiple management objectives as described in the FEIS, Chapter 1, Purpose and Needs. Treatments that may meet fuels reduction objectives, may not meet other project objectives such as forest health.

28. **The proposed action for alternatives A and E do not have the appropriate number of acres of group selection as directed by the HFQLG Act. Group Selection units are to be located primarily in CWHR 4M Stands. The NFS lands within the project area contain approximately 16,230 acres of CWHR 4M Stands. The total acres of CWHR stands proposed for treatment in both alternative A and E is 3,998. Using the total acres proposed for treatment multiplying the yearly harvest level percentage of 0.57 and on a 20-year re-entry cycle results in 456 acres. Alternative A and E have identified 284 and 326 acres of group selection respectively. As of 2009, the HFQLG Pilot Project has accomplished 7,600 acres of group selection, which represents 18 percent of the total 43,000 acres originally identified in the HFQLG ROD. We have experienced this shortfall on a project level throughout the HFQLG Pilot Project Area. The agency, by not meeting this target has failed to promote stand restructuring and has severely impaired the economic viability of these projects. We request that both alternatives have the maximum number of acres allowed under the act be placed on the landscape within the project area.** (Tom Downing, Sierra Pacific Industries, pg. 1)
